Meanwhile the investigations of Spallanzani, Wagner, Czermak, and many others, gradually increased the knowledge of the forms of the spermatozoa. Dujardin[15] was the first to consider the spermatozoa as generated from the inner layer of the seminiferous tubules, and, therefore, not as parasites. The discovery of the spermatoblasts, or immature spermatozoa, by von Siebold (Müller's *Archiv*, 1836 and 1843), soon confirmed by Kölliker and Reichert,

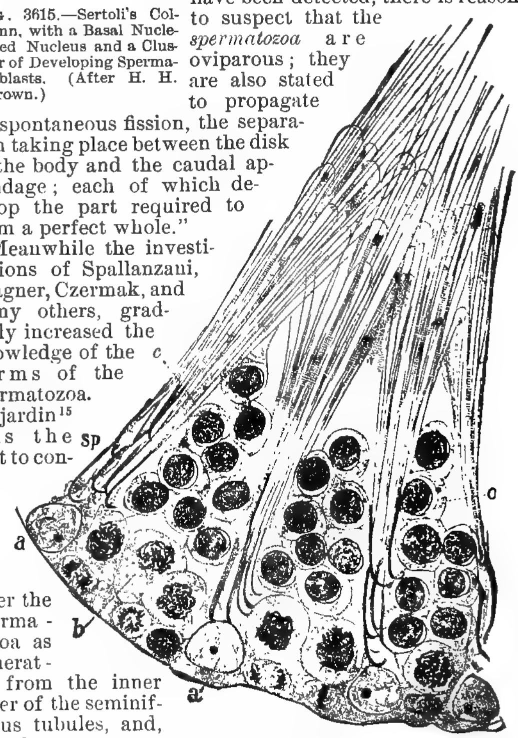

FIG. 3616.—Part of a Cross-section of a Seminiferous Tubule of a Rat. × about 750 diameters. (After H. H. Brown.)

marks an important step. Now followed a series of publications by which one detail after another was added to our knowledge. During the past twenty years there has been rapid progress, which may be said to have begun with Schweigger-Seidel's important memoir,[45] and to have made us acquainted with the minute structure of the spermatozoa, and their development. Another line of investigation was opened by O. Hertwig (1875), in following up the history of the spermatozoon within the ovum after impregnation. For further historical data see Waldeyer's address[52] (1887).

Charles Sedgwick Minot.

SPHYGMOGRAPH AND CARDIOGRAPH. Instruments for obtaining graphic representations of the pulse-movements of the arterial wall, or of the movements imparted to the chest-wall by the impulse of the heart. They cause a lever or style, which follows and magnifies the movements, to write upon a surface passing at a constant speed, and thus trace a record of the rhythmical movements in a series of curves. In order to fulfil the fundamental requirements, such instruments should accurately follow the pulse-movements, without modifying them by their own inertia; they should magnify the movements sufficiently to permit convenient study of their record; and the rate at which the recording surface moves should be reasonably constant, so that the time occupied by the various phases of the movement can be calculated.

A great number of instruments have been devised, which meet these conditions more or less successfully. The first-named requirement offers the only problem difficult of solution. The first useful sphygmograph, the curves of which have been shown to represent the actual movements of a pulsating artery, was introduced by Marey, the great master of the graphic method, in 1860. Before him the most important apparatus designed for the same end was the sphygmograph of Vierordt (1855), who failed to register the real movements of the pulse only from his anxiety to produce curves like those of the kymographion—an instrument which indicates the variations of mean blood-pressure with great exactness, but does not follow the quick and delicate variations of the pulse. The sphygmograph of Marey (originally constructed for the radial artery alone) was at once employed not only by physiologists, but by clinicians, and added sphygmography to the methods of clinical investigation. It has since been variously modified and improved, and the principle of its construction—"*sphygmographe à pression élastique*"—is the basis of most of the instruments now in common use. Moreover, it has been critically tested by other competent observers, and has been found to answer the requirements of an instrument of precision, in spite of certain limitations.[1]

ELASTIC SPRING SPHYGMOGRAPHS.—*Marey's sphygmograph.* A rather strong elastic steel spring, *a*, Fig. 3617, is fixed by one end, *b*, to a frame of brass to be applied to the forearm, while its other (free) end is provided with a thin ivory button, *c*, intended to press upon the radial artery at the wrist. The pulse-movements communicated to this button are transmitted to the lever by means of an upright toothed rod, *d*, which presses against a small similarly toothed wheel, *e*, turning on an axis to which the light wooden lever, *f*, is fastened. Every movement of the upright turns the wheel and elevates or depresses the lever. The axis of the lever revolves in a bearing in the end of the frame which rests upon the wrist. The other end of the brass frame, to which the spring is fastened, supports a clockwork,

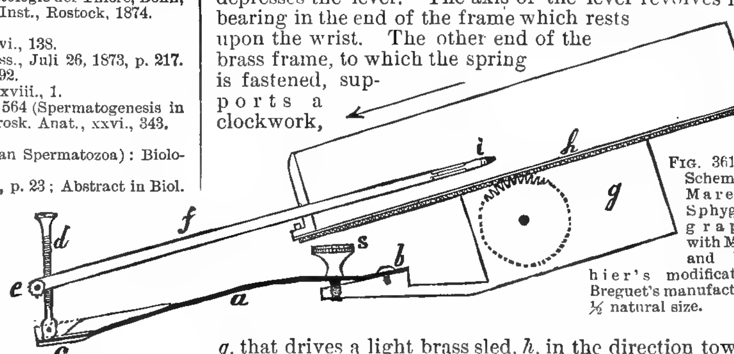

FIG. 3617.—Scheme of Marey's Sphygmograph, with Mach and Béhier's modification. Breguet's manufacture. ½ natural size.

g, that drives a light brass sled, *h*, in the direction toward the wrist, as indicated by the arrow. This sled carries the recording surface of smoked paper or glass upon which the end of the lever—a fine-pointed style, *i*—scratches its record.

The described connection between the spring and the lever, by means of the toothed rod and cog-wheel, is a modification by Mach[2] (1863) and by Béhier[3] (1868), and is now used in all the instruments made by Breguet. The rod is movable on an axis in a brass plate on the free end of the spring, so that it can be laid flat upon the latter while the sphygmograph is being adjusted to the arm, and lifted up against the toothed wheel of the lever when the instrument is set in action. The spring itself keeps it closely applied to the cogs of the wheel.

The pressure of the spring upon the artery is modified by means of the screw *s*, which presses the spring downward with greater or less force. While by this means the pressure can be varied, it cannot be measured. To obviate this defect Burdon-Sanderson (1867) introduced a modi-

fication, by which the instrument is at the same time more securely fixed to the wrist. Removing the wings by which Marey binds the frame upon the forearm, he

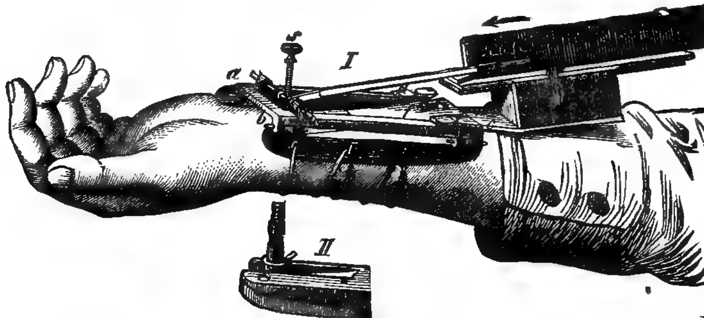

FIG. 3618.—*I*, Marey's Sphygmograph. Applied; *II* shows the manner in which the upright toothed rod of Béhier is joined to the end of the spring. (Rollett, in Hermann's Hdb. d. Physiologie, Bd. iv.)

adjusts to the end of the instrument (between the letters *a* and *b* in Fig. 3618) "a rectangular block of brass, by the under surface of which [covered with ebonite] it rests on the tendon of the *flexor longus pollicis*, and on the space between that tendon and the spine of the radius; the block being kept closely applied to the surface by means of a strong elastic band which encircles the wrist."[4] By means of a screw the distance between the ebonite surface and the frame is varied at will and the pressure modified; the amount of the pressure is measured by the deflexion of the spring (the distance between the spring and the lever) as determined by experimental test. Mahomed[5] (1872) substituted for the screw *s*, which in Marey's sphygmograph varies the pressure of the spring, an excentric wheel M (Fig. 3619), graduated in accordance with the degree of pressure, so that the latter may be read off at once.

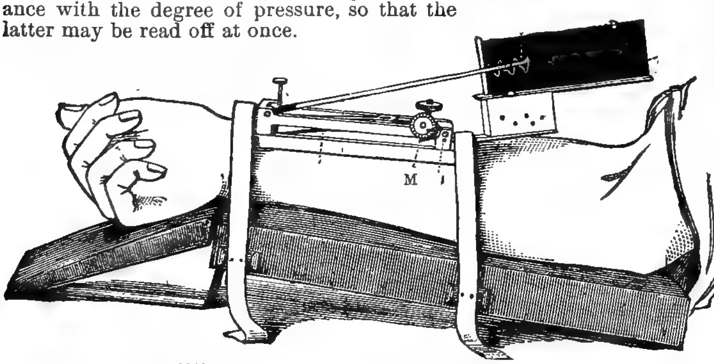

FIG. 3619.—Mahomed's Sphygmograph, Applied. (Bramwell.)

Marey's instrument is fixed to the forearm by means of japanned wings hinged to the frame, which are provided with hooks, and a silken cord passed under the arm from hook to hook. This mode of adjustment is defective. Mahomed's sphygmograph is more securely attached, by

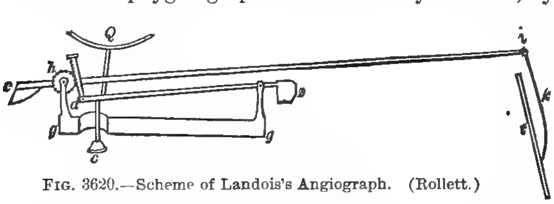

FIG. 3620.—Scheme of Landois's Angiograph. (Rollett.)

means of two straps, one at each end of the frame, to a supporting pad placed under the arm, as seen in Fig. 3619.

INSTRUMENTS IN WHICH THE PRESSURE IS EXERTED BY WEIGHTS.—Instead of the elastic spring pressure, methods have been devised for applying the pressure by weights, which afford the advantage of numerical accuracy. Such are the modification of Marey's sphygmograph by Baker[6] (1867), the angiograph of Landois[7] (1872), the sphygmograph of Sommerbrodt[8] (1876), and the *sphygmographe passif* of Brondel[9] (1878). Baker and Brondel replace the steel spring of Marey's instrument by sliding weights; the most important contrivance for carrying out the principle of pressure by direct weight, however, was invented by Landois.

Landois's Angiograph.—On the proximal end of a plate, *g*, *g*, (Fig. 3620), that serves as the base of the instrument, is balanced on an axis the solid rod *d*, *z*, which takes the place of the spring in Marey's sphygmograph; to its longer arm, near *d*, are attached, below, a stem carrying the button *c*, which explores the artery, and above, a stem carrying a dish or scale, *Q*, for holding the weights, and a toothed rod which, as in Béhier's modification, moves the toothed wheel *h*, attached to the spindle of the writing lever. This lever bears upon its extremity a light needle, *k*, hung from the joint *i* in such manner that it falls by its own weight upon the smoked plate *t*; this plate—the recording surface—is moved by clock-work at right angles to the plane of the lever (and to the forearm).

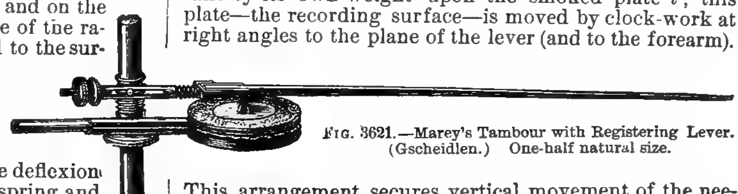

FIG. 3621.—Marey's Tambour with Registering Lever. (Gscheidlen.) One-half natural size.

This arrangement secures vertical movement of the needle instead of the curved movement of the style of Marey's sphygmograph, as well as the least possible friction in the tracing apparatus, but at the same time involves a clumsiness which detracts from the convenience of the instrument. The lever itself, as well as the rod *d z*, with all its attachments, being balanced by counterpoises, *e* and *z*, the pressure upon the artery is exerted only by the weights placed in the scale.

Sommerbrodt made use of a like accurate method of pressure by weights in his somewhat complicated modification of Marey's sphygmograph.

TRANSMISSION SPHYGMOGRAPHS, POLYGRAPHS, PANTOGRAPHS.—A new principle in the construction of pulse-writers was introduced by Marey (1863), following the methods of Upham and Buisson, in his instruments "*à transmission.*" With the help of a suitable mechanism the pulsatory movements are conveyed to a Marey's *tambour* or tympanum, which is put in communication, by a flexible tube, with a second tympanum. The second tympanum carries the writing lever.

The tympanum is a shallow capsule of metal covered by a caoutchouc membrane, the centre of which bears a

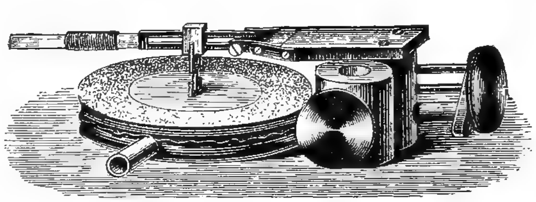

FIG. 3622.—Marey's Registering Tambour; new construction. (Gscheidlen.) Natural size.

very light round metal (aluminium) plate. In the second (or registering) tambour this plate is provided with a

wooden bridge or knife-edge upon which the writing lever rests. Figs. 3621 and 3622 show the details of construction of this apparatus, now well known in the physiological laboratory. The expanding movement of the artery compresses the air in the first (or receiving) tambour and forces a part of the contained air into the second tympanum, whose membrane is thereby raised and lifts up the lever placed upon it. The lever magnifies the movements.

The recording surface may be so large and so constructed

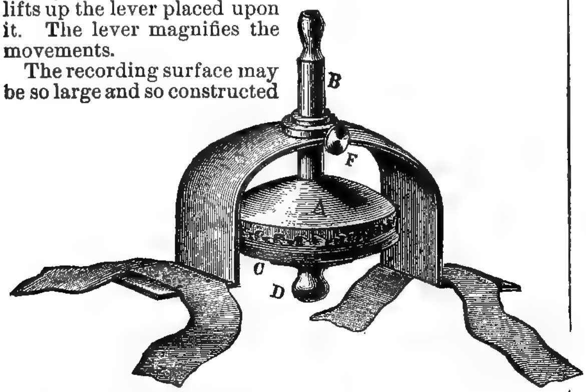

Fig. 3623.—Receiving Tympanum of Brondgeest's Pansphygmograph. (Gscheidlen.) One-half natural size.

that a number of levers can register upon it at the same time, one exactly under the other, and the pulse-movements from two or more sources can be inscribed upon it synchronously; such instruments have been called *polygraphs.*

Sphygmographs of this construction differ mainly in the mode of application of the receiving tambour to the pulsating surface; many of them can be applied to any pulsating artery, as well as to the chest-wall over the impulse of the heart, and are known collectively as

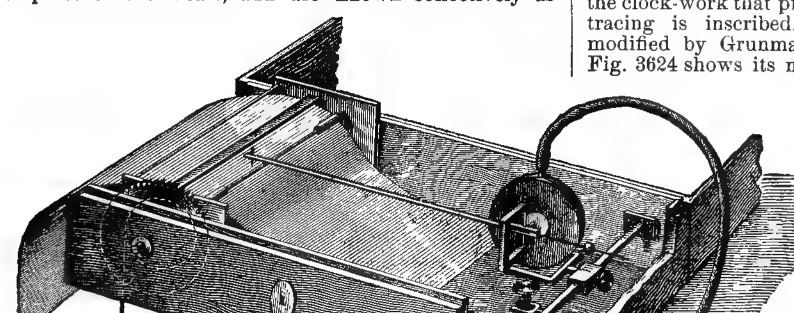

Fig. 3624.—Grunmach's Modification of Meurisse and Mathieu's Polygraph. (Gscheidlen.) One-fourth natural size.

pantographs. Many cardiographs (see below) are constructed on this principle, which was, indeed, first used for demonstrating the movements of the heart by Upham, Buisson, and Marey. Brondgeest (1873), in his *pansphygmograph,* devised a mechanism for applying the tambour to all pulsating surfaces; the capsule A (Fig. 3623), whose elastic membrane, C, is provided with a button, D, is held over the vessel by means of a metal bow in which its short metal tube, B, is fastened by a screw, F, in such manner that the button bears upon the artery with the necessary degree of pressure. The tube B is connected by a caoutchouc tube with the registering tambour. Two systems of tambours, or three,

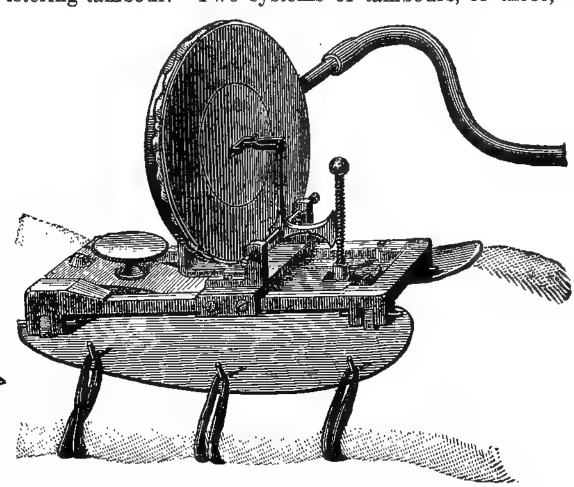

Fig. 3625.—Marey's *Sphygmographe à transmission.* (Ozanam.)

can be employed to register movements upon a revolving cylinder simultaneously.

Meurisse and Mathieu (1875) made use of a more complicated receiving apparatus, adding spring-pressure; they also placed the recording apparatus, for greater clinical convenience, in a portable box which contains the clock-work that propels a strip of paper on which the tracing is inscribed. This sphygmograph has been modified by Grunmach (1876) and by v. Knoll (1879). Fig. 3624 shows its modern form. The exploring button D is detached from the capsule; it is carried on the end of a curved steel spring, B C, rising from a horse-shoe plate, which serves as the base; the degree of pressure of the spring is regulated by the screw E. The capsule is held over the button by two vertical rods fixed upon the base-plate, so that the stem of the button touches the centre of the membrane of the tambour. The latter is set higher or lower by a ratchet mechanism. The use of the spring-pressure in connection with the transmission-apparatus seems to have been suggested by Burdon-Sanderson's cardiograph (see below).

In Marey's *sphygmographe à transmission* (1878) (Fig. 3625), spring-pressure is also used, the mode of application being the same as in his elastic-spring sphygmograph; the same frame, without the clock-work, carries a steel spring and a Béhier-Mach grooved stem, which rests against one end of an angular lever; the other end of this lever touches the centre-plate of the receiving tambour, which is set upright facing the wrist. Dilatation of the artery raises the spring, presses the lever against the membrane of the tambour, and, by compression of the air within, raises the membrane of the recording tambour and lifts the writing lever.

Keyt,[10] of Cincinnati, starting with a "sphygmometer" of his own invention, similar to the old sphygmometer of Hérisson and the sphygmoscope of Naumann, evolved the "compound sphygmograph," which Fig. 3627 shows in its most complete form—a transmission sphygmograph, in which water is used as the medium, instead of air. His sphygmometer was a graduated glass tube, eight or

ten inches long, with an exploring "base" of brass (Fig. 3626), "semicircular in form, with an oblong free edge below, and a shallow neck into which is inserted, air-tight, the glass tube." The free edge of the base, one and three-eighths by three-eighths inch, is closed by a rubber membrane. This base is used in the perfected instrument for receiving the pulse movements. When the base is pressed upon the artery, the water in the tube follows the movements of the arterial wall. He then closed the top of the tube (filled with water) by a rubber membrane, and placing on this a pin and lever, was ready to register the enlarged movements on a passing plate. In the complete instrument (Fig. 3627) there are supplied two exploring bases, each with its tube and lever, one of which registers exactly below the other. The communicating tubes are made of stiff rubber, or of glass with rubber joints, so that the bases can be freely moved. The upper end of the tube is now a metal cylinder closed by a rubber membrane. Each base can also be put in communication with a manometer tube indicating the degree of pressure applied. The registering plate is driven by a clock-work, and receives, besides the tracings of the lever, the simultaneous markings of a chronograph. The instrument thus becomes one of the best polygraphs, and lends itself especially to the study of the synchronism or succession of events in the circulation.

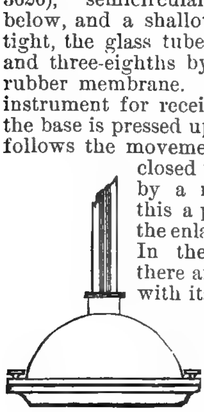

Fig. 3626.—Base of Keyt's Sphygmometer and Sphygmograph. (After Keyt.)

Keyt asserts that in his manner of employing water as the medium for the transmission of movements, the inertia of the water does not become obnoxious, and its power of transmission is greater than that of air. His tracings seem to bear out this claim. But when Ozanam, in his sphygmograph,[11] resorts to the much heavier medium mercury, the resulting curves are scarcely more than the records of rhythmical oscillations of the mercury.—— Facility of application and clinical convenience have been consulted in two instruments, which have been used more extensively by physicians, perhaps, and which have bred more amateur sphygmographers than any others, in America as well as in England and Germany—those of Pond (Vermont, 1877) and of Dudgeon (England, 1878–80).

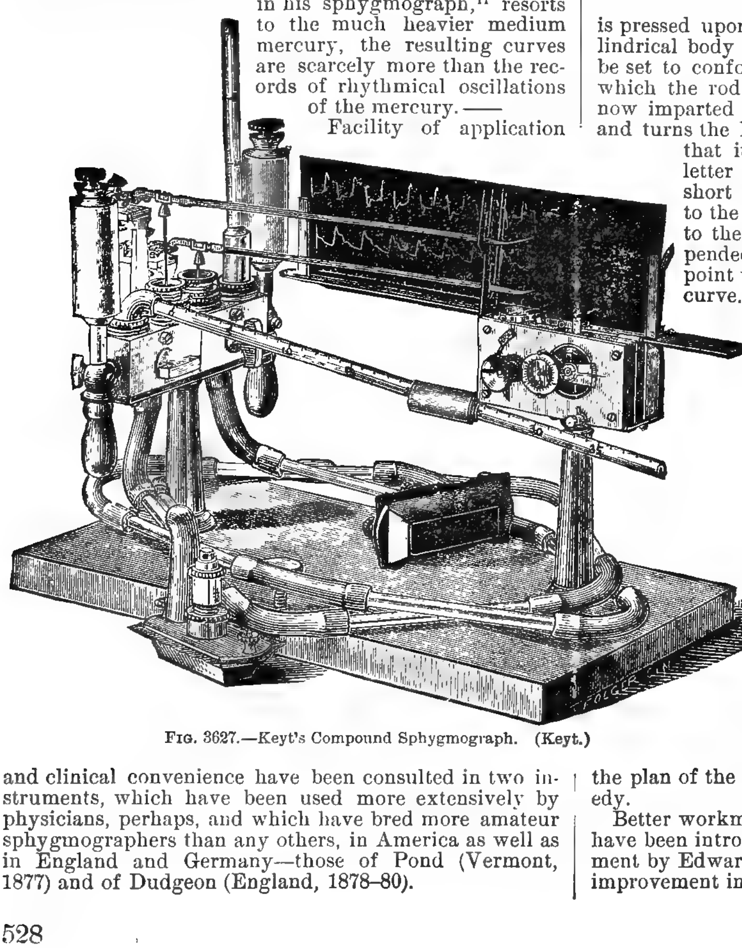

Fig. 3627.—Keyt's Compound Sphygmograph. (Keyt.)

Pond's sphygmograph, in its present form, when in use, is held in the fingers by the hollow cylindrical body *a*, (Fig. 3628) and the necessary pressure is thus exerted on the artery more readily, and quite as steadily, as by use of the arm-rest furnished with the instrument in its earlier phases. The foot of this body is an oval metal capsule, *b*, closed by a pure-rubber cap; the base is thus made of a slightly stretched elastic membrane, which is made more or less tense according to the pressure used. Upon this membrane rests a small metal plate bearing an upright rod, which moves loosely within the body and terminates in the button *c*. From the upper part of the body spring two metal arms, one of which supports the clock-work *d*, and a stage, *e*, for the card-board or mica slide on which the trace is written (the slide moves, in the figure, at right angles to the plane of the paper, and toward the spectator). The other metal arm bears the system of levers and the writing-needle.

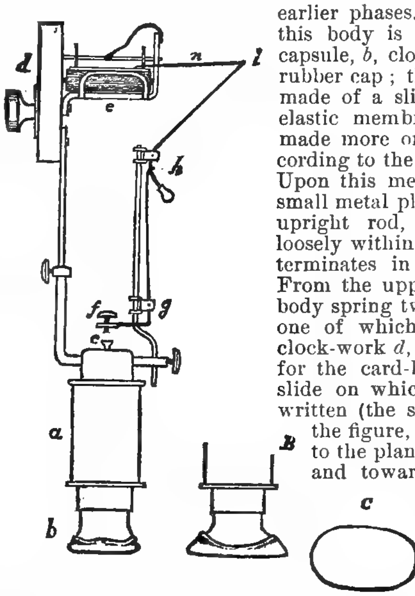

Fig. 3628.—Scheme of Pond's Sphygmograph. *B*, Side view of the base; *C*, shape of rubber membrane closing the bottom of the base. One-half natural size.

When the instrument is pressed upon the artery the rod concealed in the cylindrical body rises and touches the screw *f*, which can be set to conform to the pressure, *i.e.*, to the height to which the rod is lifted; any further upward movement now imparted to the rod by the pulse raises the screw and turns the lower lever about the pivotal point *g*, so that its upper end moves outward toward the letter *h*. This end, by a loop, embraces the short arm of the second lever, and, pushing it to the right (in the figure), moves its long arm to the left. From the end of this lever is suspended, by the loose joint *i*, the needle *n*, whose point rests upon the slide and traces the pulse-curve. The short arm of the upper lever ends in a counterpoise, which by its weight secures the return of the lever when the upward pressure is withdrawn. In this instrument, the pressure made over the artery is that of the more or less tense rubber membrane at the base.

The defects of this instrument are obvious. The weight of the levers and their counterpoise is so great, as compared with that of the rod, which lies loosely upon the membrane of the base, that the inherent vibrations of the apparatus make themselves felt in the curve. The excursions of the needle are limited to the distance of the upper lever (at rest) from the stage on which the slide travels, which is not much over half an inch; the tracing cannot be higher than this; if the lever strikes at either extremity of its course, the curve is vitiated. This imperfection could be easily removed; the former defect pertains to the plan of the instrument, and is more difficult to remedy.

Better workmanship and some modifications in detail have been introduced in the construction of this instrument by Edwards (Buffalo, 1880), but without apparent improvement in the results, as Hopkins' curves testify.[12]

Dudgeon's sphygmograph combines in an ingenious manner the steel spring of Marey with the registering mechanism of Pond. A rather short steel spring, A, Fig. 3629, whose pressure is regulated by a Mahomed's eccentric, N, indicating ounces, is provided at its free end with a movable exploring button, B, and transmits its movements to the writing-needle L, by a system of levers on the plan of Pond, as seen in the illustrations (Figs. 3629 and 3630). The whole instrument is given a more compact form, and is fastened to the wrist by a single strap, the tightening of which can be usefully controlled by the fingers of the experimenter. This mode of application has some advantages. The use of the steel spring is a decided improvement upon the rubber membrane of Pond's sphygmograph; the system of levers is, however, as in Pond's, subject to vibrations of its own which are apt to mar the curve.

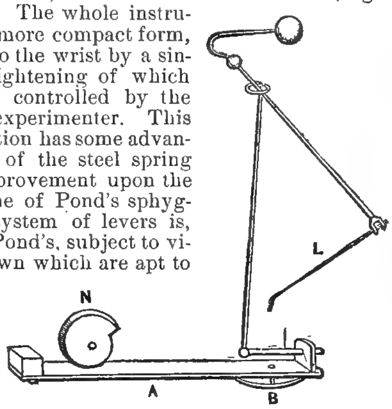

Fig. 3629.—Scheme of Dudgeon's Sphygmograph. (Dudgeon.) Natural size.

CARDIOGRAPHS.—The principle of transmission was first carried out in the older form of Marey's cardiograph (1865) (Fig. 3631). The receiving mechanism of this instrument was, however, defective and has been replaced by a later device in 1875. The transmission instruments intended for the heart are now constructed with a receiving tambour, whose earliest and simplest form was embodied in Brondgeest's pansphygmograph (1873), already described. Burdon-Sanderson, in the same year, added the elastic curved spring, and supported the exploring tambour on an adjustable tripod which was fastened over the heart by straps passing round the chest. The receiving apparatus of Meurisse and Mathieu (1875), and its modifications by Grunmach and v.

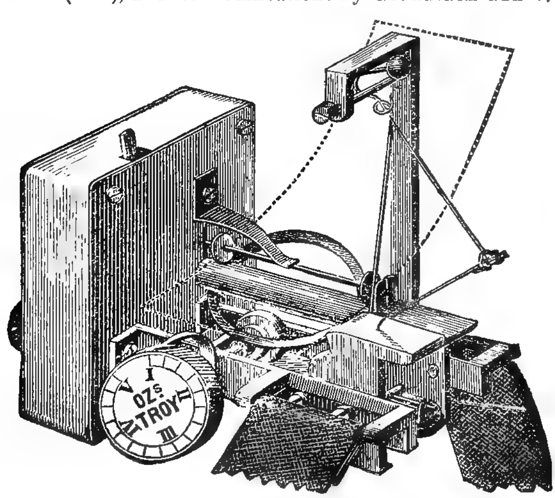

Fig. 3630.—Dudgeon's Sphygmograph. (Dudgeon.) Natural size.

Knoll (1876, 1879), which also presses the exploring button upon the pulsating surface by means of a curved spring, has been described before. Marey (1875) improved his instrument by inclosing the receiving tambour, furnished with a central button, in a cylindrical capsule, in which a spiral spring exerts the necessary pressure (Fig. 3633). In all these transmission instruments the registering apparatus is constructed on similar principles.

Keyt's compound sphygmograph, transmitting movements through water, as before described, is as well adapted for recording the apex beat as the arterial pulsations.

Marey's sphygmograph in its ordinary forms has also been extensively used for the exploration of the heart's impulse, and with excellent results, *e.g.*, by Landois. It

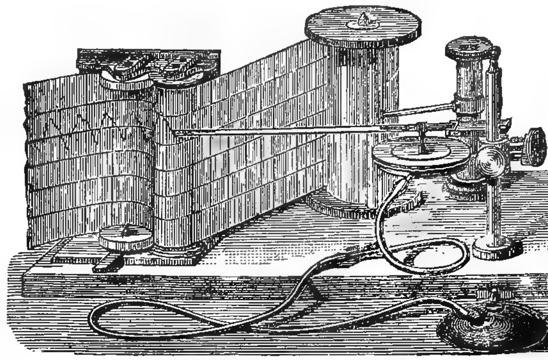

Fig. 3631.—Marey's Cardiograph, original form. (Ozanam.)

has also been specially adapted to use as a cardiograph by Galabin[13] (1872). He suspends a Marey's sphygmograph, of the Mahomed pattern (so modified that the magnifying power of the lever can be varied at will from ten to about a hundred), from two transverse rods held

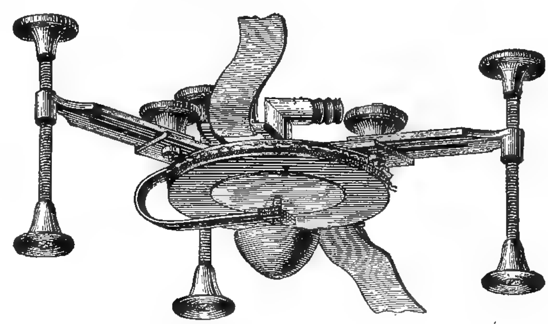

Fig. 3632.—Burdon-Sanderson's Cardiograph, Receiving Apparatus. (Gscheidlen.) Natural size.

up by four vertical rods inserted into two bars of wood covered with leather, which rest upon the chest. The attachment of the transverse rods to the vertical supports permits their being raised or lowered at either end, so that the instrument can be levelled, and the bars can be

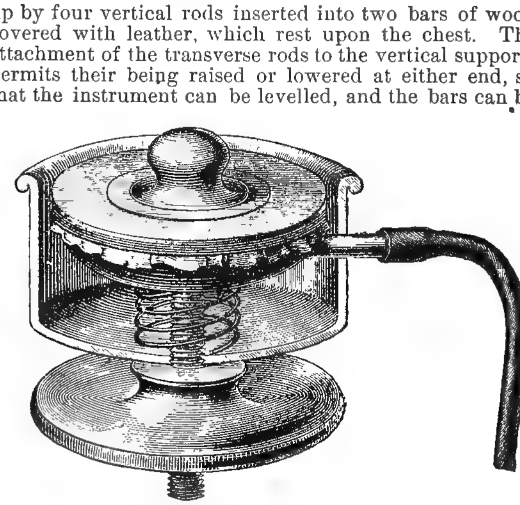

Fig. 3633.—Marey's Cardiograph, Receiving Apparatus of later form, 1875. (Gscheidlen.) Natural size.

separated to a width of nearly five inches, and adapted to a chest of any size or shape. The whole is fixed upon the chest by straps passed round the body.

Pond's and Dudgeon's sphygmographs have but a limited use as cardiographs, and give curves which are imperfect in some details.

For specimens of tracings obtained by various cardiographs, see article Pulse, Arterial, section Cardiogram.

Hydrosphygmographs. — The pulsating movement constituted by the increase and decrease of volume of an entire extremity, caused by the arterial diastole and systole, can be recorded by instruments combining the receiving apparatus of a plethysmograph with the registering mechanism of a transmission sphygmograph. Such are the hydrosphygmographs of François-Franck[14] (1876) and of Mosso[15] (1879). The latter, especially, affords curves very similar to those of the ordinary sphygmograph. The receiving apparatus of Mosso's instrument consists of a large glass cylinder filled with water, into which the forearm can be inserted, air-tight, through an opening closed by a rubber sleeve. The cylinder is suspended from above by a chain; it communicates by its smaller end with a reservoir of water which regulates the hydrostatic pressure; by another opening on top it is connected, by means of a flexible tube, with a Marey's tambour and lever. The curves thus obtained record the pulsatory changes in volume of the forearm. It is not to be expected that they agree perfectly with those obtained with the sphygmograph; the latter registers the changes taking place in the short piece of artery touched by the exploring button—practically one cross-section of the arterial system; the hydrosphygmograph registers the increments of volume of all sections of the arterial system of the forearm and hand at once, and since these increments do not take place at exactly the same time, a certain amount of fusing of details in the curve must result; that this fusion is, under ordinary circumstances, small, is explained by the high rate of transmission of the pulse-wave.

The instrument lends itself especially to investigations requiring continuous registration for hours, uniform external pressure upon the blood-vessels uninfluenced by their own changes of calibre, and immutable local conditions during changes in position and action of the body; and it permits the synchronous registration of curves of the heart's impulse, the carotids, the respiration, etc., by other instruments. It has yielded valuable results in the hands of its author.

The Recording Surface.—Some of the transmission instruments register upon a revolving drum, such as is used in the graphic instruments of the physiological laboratory (see Fig. 3631). Other sphygmographs are constructed for registering upon strips of smooth paper or glazed card-board, or upon slides of glass, smoked. Pond, I think, was the first to recommend slides of mica, useful by virtue of their lightness, and because, being very thin, they can be used as negatives for direct photographic reproduction.* Mica slides must be selected with care; those which are warped must be rejected, especially for Marey's instruments; in Pond's and Dudgeon's they are excellent substitutes for card-board. Paper and card-board answer well in the instruments which write with a loosely suspended needle; but the tracings cannot be multiplied as readily as when taken on transparent slides. Thin plate-glass is the best material for use in Marey's and in Keyt's sphygmographs, because of its smooth and level surface.

Glass and mica are best smoked in a large gas flame, which yields a very even coat of soot of any desired density. Paper must be smoked over a flame emitting less heat and more smoke, as an open petroleum flame, and this requires greater skill to obtain an even coating. In either case the coating of smoke should be as thin as is compatible with the purpose.

The curves are fixed by dipping the slides, of whatever material, into a thin, quickly drying varnish. Perhaps the most useful varnish is a concentrated solution of the best white shel-lac in alcohol. Some prefer the varnishes in use by photographers.

The method of writing with ink upon a glazed paper surface, by means of a pen or marker at the end of the lever, as in the older Marey instruments, has been abandoned, mainly because the friction involved in this method is far too great to give delicate traces.

In the foregoing account of instruments, no attempt at completeness has been made. Many other instruments have been invented; some have been confined to the physiological laboratory, or employed only by the inventors; others have been quickly abandoned. The sphygmographs in present use in medical practice, hospital or private, are chiefly the spring sphygmograph of Marey and its modifications by Burdon-Sanderson and by Mahomed, Grunmach's modification of the transmission sphygmograph of Meurisse and Mathieu, Pond's, and Dudgeon's.

Taking the Tracing.—To give in this place detailed directions for the application of each instrument were fruitless. The use of the sphygmograph is not easily learned, and skill in its application can be acquired only in conjunction with knowledge of the tracing and the pulse. The serious study of sphygmography is best begun with a Marey, Mahomed, or Burdon-Sanderson; although these are difficult to operate, they sooner teach the much more difficult art of recognizing whether or no the trace taken is a correct and adequate representation of the pulse explored.

In order to write a correct sphygmogram it is necessary (1) to explore the artery at the best possible point; (2) to exert just the requisite pressure upon it, neither too much nor too little; and (3) to let the lever write with the least possible friction.

1. The radial artery is best reached just before it crosses the end of the radius. Beginners often err, especially when using spring sphygmographs, in applying the exploring button higher up. At the point indicated the artery is most superficial, and rests upon a firm support; above this point it lies upon the pronator quadratus muscle and is embedded in abundant adipose tissue. In all sphygmographs the exploring mechanism and the means of fixing the instrument are constructed with special regard to this artery, but they do not all adjust themselves equally well even to this locality. In Marey's instrument, notably, the correct adjustment of the pressure upon the artery is sometimes impossible with the mechanical means provided; the best tracings are often obtained by holding the lower end of the instrument in the fingers. With Dudgeon's sphygmograph the exact spot and the proper pressure are more easily found, most easily with Pond's, and with the movable bases of transmission sphygmographs. Care must be taken to place the button or explorer exactly over the artery; if the button lies to one side of it, the curve is stunted in its details; if it slips off and lies alongside the artery, there often results a so-called negative curve.

The arm should be slightly flexed at the elbow, the hand supinated and fully, but not forcibly, extended at the wrist. A rest for the hand, as the wedge-shaped cushion of Mahomed, is often useful in connection with the spring sphygmographs, but not indispensable. The rest provided for the original Pond's was a useless encumbrance, and has been abandoned.

2. Next to the most available locality, the degree of pressure is of greatest importance. The exploring button or base should come into such (mediate) contact with the arterial walls that it must follow their movements closely. If too far removed (too lightly applied), it receives the impulse of the artery too feebly or too late, and fails to record them in proper extent or time; if pressed too forcibly upon the artery, the expansion of the latter is diminished and delayed: in either case the curve is too small and otherwise deformed. Figs. 3634 to 3636 afford examples; also Fig. 3637, *e* and *f*.

With insufficient pressure, the curve is small and inexpressive, and the secondary waves are ill developed (Figs. 3634, *a*; 3636, *a*.) As the pressure is increased the secondary events become more pronounced and characteristic, and the curve grows higher. With a pressure exactly

* Most of the tracings illustrating this article, and the article Pulse, were taken on mica; some on glass.

suited to the pulse, the details of the curve are most perfect, and the secondary waves, especially the dicrotic, most distinctly delineated (Figs. 3634, *b*; 3635, *b*; 3636, *b*). Still increasing the pressure, we see the curve diminish in amplitude, the up-stroke being shortened (expressing a celerity greater than the actual); but the apex is still sharp, and the predicrotic wave well expressed, while the dicrotic elevation becomes smaller (Fig. 3635, *c*,

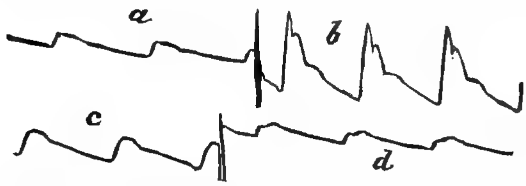

FIG. 3634.—Radial Pulse of Healthy Man, aged fifty. Dudgeon's. *a*, Pressure, 1 oz.; *b*, 3 oz.; *c*, 4 oz.; *d*, 5 oz., the instrument meanwhile remaining *in situ*.

d). With still increasing pressure the curve becomes much smaller, the upstroke short, the first secondary wave is much enlarged, and the dicrotic wave disappears (Fig. 3634, *c*, *d*). The resulting trace is that of a very hard, even anacrotic curve (Figs. 3634, *d*; 3636, *c*), such as only highly atheromatous arteries could truly give. Still stronger pressure finally suppresses the pulse altogether.

The evident importance of this point, and the desire, by means of the pressure found necessary, upon trial, to

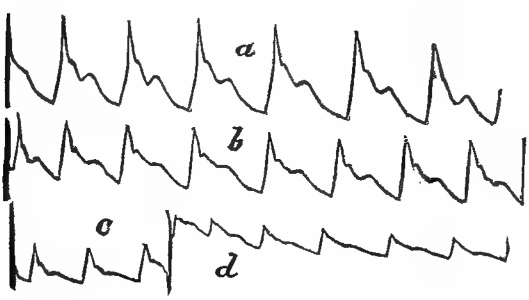

FIG. 3635.—Healthy Boy, aged six. Dudgeon's. *a*, Pressure, 2 oz.: *b*, 3 oz.; *c*, 4 oz.; *d*, 5 oz.

evoke the most perfect curve, to estimate the blood-pressure within the living artery, has led sphygmographers to devise means not only for varying, but for expressing the pressure of the instrument in numbers. This object has been accomplished only in those pulse-writers which exert their pressure by weights instead of springs, as in Landois's angiograph—an instrument of great scientific accuracy—and in Keyt's sphygmograph by means of the manometric tube. But even in this case the weights indicate only the pressure upon the skin, not that upon the

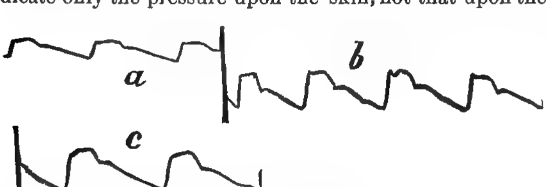

FIG. 3636.—Woman, aged forty-eight. Dudgeon's. *a*, Pressure, 1½ oz.; *b*, 2½ oz.; *c*, 3 oz.

artery, which must be less than the former, by the variable amounts of elastic resistance of the intervening skin, fascia, and neighboring tendons. This source of error, and the impossibility of estimating the force exerted in fastening the sphygmograph upon the wrist, has made all attempts at measuring the pressure with other instruments illusory. The devices to this end of Burdon-Sanderson and of Mahomed furnish numbers of only approximate value, useful when the pressure is varied while the instrument remains *in situ*, but not comparable with observations at different times or on different arteries—not at all comparable with the numbers expressing the pressure in other instruments.

Sphygmographs in which the pressure is controlled by the hand alone, as in Pond's, are most easily adjusted, and the pressure can be more evenly applied in this way than would seem possible.

Even if the degree of pressure could be accurately known, it would still give no correct information as to the blood-pressure; the form of the pulse-curve assists in judging of the comparative degree of tension of the artery; but accuracy in determining the compressibility of the pulse must be sought by aid of other instruments, such as Waldenburg's Pulsuhr or Basch's sphygmomanometer.

3. When the lever of the instrument meets with too much friction the curve is altered in the same direction as when excessive pressure is used; it loses in delicacy, the minor events are obliterated, and the apex is apt to be blunted or flattened. Hence it is essential that the recording surface be very smooth, and smoked only just enough to make the trace distinct. For the same reason, the method of writing with an inked style upon a glazed paper has been almost discarded. Moreover, the lever should not bear too firmly upon the surface.

In judging of the adequacy of a curve, two points are of special importance: the apex should be sharp, and there should be no evidence of vibrations due to inertia of the instrument itself. A curve with a rounded, blunt, or truncated apex is to be suspected until all source of error is eliminated. This defect is common in the tracings by the spring sphygmographs, and is owing either to excessive pressure (too hard a spring, as in many of Marey's instruments) or to undue friction in the writing apparatus. Vibrations by inertia, exaggerated excursions of the needle, are apt to deform the curves by Pond's and Dudgeon's instruments. Not only may evident and avoidable monstrosities of curves * result in this manner, but there is a general tendency to exaggerations of certain events in the curve.† The fall of the lever is apt to be too rapid and too sudden, deepening the depressions preceding the secondary waves, and hence also increasing the size of the latter. (Compare Fig. 3637, *b*, *c*). These sphygmographs produce dicrotism too easily, with lower fever-temperatures, than the spring sphygmographs do, and generally their curves have the look of low tension. On the other hand, the frequently exaggerated predicrotic wave sometimes gives the appearance of higher tension than is found with other instruments.‡ This error in interpretation is in a measure guarded against by comparing the relative height and position of the predicrotic with the dicrotic wave.

It is evident, therefore, that the instruments described differ greatly in the two practically important respects of (1) facility of application and (2) accuracy of results. Unfortunately, those which excel in the one are most apt to fail in the other. In ease of handling, Pond's and Dudgeon's sphygmographs take the first rank, and the transmission instruments with movable bases, especially Keyt's, are likewise easy of adjustment. Among the spring sphygmographs, Mahomed's and Burdon-Sanderson's are more readily applied than Marey's own. For

* Broadbent (British Medical Journal, March 26, 1887, i., p. 657) gives a curve to illustrate the vagaries of Dudgeon's sphygmograph, but which shows, rather, the inexperience of the operator who would seriously present it as the curve expressing the movements of the artery. Bad curves can be taken with a Marey as well, erring mostly in an opposite direction, as the student can best learn from the excellent article "*Ueber fehlerhaftes Pulszeichnen*," by Wolff, in the Prager Vierteljahrsschrift f. prakt. Heilk., 1871.

† A glance at the curves taken with an Edwards sphygmograph (modification of Pond's), and published by Dr. H. R. Hopkins (Medical Press of Western New York, November, 1885, pp. 7. 9, 10, 12), will illustrate this point; some of these curves reproduce only the vibrations of the instrument itself, *e.g.*, Fig. 5 (M. S.), 4 (B.), and 6 (E. H.).

‡ In Guy's Hospital Reports, 1881, p. 337, Mahomed reproduces a tracing by Pond's to show "very high tension," which by no means shows it. He was evidently led into error by comparing Pond's curves with those of his own sphygmograph, without due allowance for inherent differences in the action of the two instruments.

his angiograph Landois himself does not claim clinical convenience. In accuracy of results, however, the sphygmographs named rank in nearly inverse order. Curves obtained with different instruments in different cases cannot be directly compared, no matter how perfect of their kind they may be. Those written with Marey's spring sphygmograph are universally accepted as reproducing most exactly the movements of the arterial wall, and to them all others must be referred. The use of Pond's and Dudgeon's sphygmographs, so thoroughly convenient for every-day practice, can be recommended only to those who are familiar with the working of the spring sphygmographs; their convenience is offset by the danger of misinterpretation from neglecting to allow for the inherent defects of the instruments.

For illustrations of the tracings afforded by a number of sphygmographs and cardiographs the reader is re-

SPINAL ABSCESS. Usually in the course of caries of the spine, or Pott's disease, suppuration takes place. To the collections of pus which result may be given the generic term "spinal abscess." Surgeons, however, have been long in the habit of naming these collections after the regions in or near which they first make their appearance on the surface. Hence the terms cervical or post-pharyngeal (retro-pharyngeal), dorsal, lumbar, iliac, psoas abscess, etc., depending on the locality diseased or invaded.

FORMATION OF SPINAL ABSCESS.—As in caries or ulceration of bone elsewhere, granulations rapidly spring up in the affected vertebra, raising the periosteum, which in turn becomes much thickened and vascular, and is itself often penetrated by the same granulations. Thus not only is pus formed, but at the same time the soft parts outside the periosteum become gradually inflamed, infiltrated, and thickened, and ultimately constitute the chief boundary wall of the purulent collection. Where the caries originates in the centre of one of the vertebral bodies these changes progress very slowly, and adjoining vertebræ may become invaded before pus appears external to the bone. Indeed, the abscess may never become visible (caries sicca), remaining within the limits of the bone. To this variety the term "vertebral abscess" has been given. The tendency, however, is to the formation of large collections, which usually take a downward course, limited only by the resistance of the soft parts. The pus resulting is at first usually curdy, but later becomes more homogeneous, though seldom laudable. Bone-dust and fragments of necrosed bone are also occasionally present.

The occurrence of spinal abscess is always a serious complication of Pott's disease, and is probably the most common cause of death. It has been noticed also that the more circuitous the route taken by the pus, the more serious are the consequences likely to be.

The variety of spinal abscess will depend on the region affected with caries, on the resistance offered to the pus as it leaves the diseased bone, and on the route subsequently taken to reach the surface of the body.

While caries of the vertebræ is by far the most frequent cause of spinal abscess, it is well to mention that collections of pus due to other causes are occasionally found in the immediate vicinity of the spinal column, and may receive the same name. Thus we occasionally find abscesses in the cervical region due to tubercular and syphilitic ulcerations about the pharynx, while a more acute form is now and then met with as a complication of acute pharyngitis and quinsy. So psoas abscess may occur quite independently of disease of the vertebræ.

CERVICAL ABSCESS, termed also *post-pharyngeal* and *retro-pharyngeal abscess.*—This usually results from disease of one or more of the cervical vertebræ, and is often the first indication of caries. It is, however, not invariably due to this cause. The writer has seen retro-pharyngeal abscess, evidently following tonsillitis or pharyngitis, in children, where there were restrained movement of the neck, retraction of the head, and other signs of caries. The abscesses were evacuated behind the sterno-mastoid muscle, when all symptoms suddenly disappeared and complete recovery followed. Usually when the disease is confined to the anterior or lateral surface of the bodies of the vertebræ, a soft, fluctuating, and somewhat œdematous swelling is to be seen and felt bulging forward on the posterior wall of the pharynx. This may increase to such an extent as to interfere with deglutition, and even to cause troublesome and alarming dyspnœa. Purulent collections from cervical disease, however, more frequently proceed in a lateral or postero-lateral direction, between the longus colli and scaleni muscles, first appearing in the posterior triangle of the neck, behind the sterno-cleido-mastoid muscle. In very exceptional cases cervical abscess points posteriorly near the ligamentum nuchæ, and still more rarely the pus gravitates downward into the posterior mediastinum, whence it may enter the pleura or pericardium. Cervical abscess has likewise been known to penetrate the œsophagus and trachea, and in one case reported, first appeared in the axilla.

The *diagnosis* of abscess from cervical disease is seldom difficult, if due attention be paid to the signs and symptoms of bone disease invariably present, namely, stiffness of the neck, with limited movement of the head, deformity, and increased pain on pressure over the cervical spine.

The *dangers* of cervical abscess are chiefly dyspnœa and suffocation, the latter from sudden bursting of the collection, especially during sleep, and the entry of pus into the air-passages. Gautier collected 97 cases, of which

41 proved fatal, but this is an exceptionally large mortality, and it is probable that not more than from fifteen to twenty per cent. terminate in death.

The *treatment* of all the forms of spinal abscess will be described further on in this article.

Dorsal Abscess.—By this is meant usually a collection of pus, the result of caries of the dorsal vertebræ, which has passed backward between, or external to, the transverse processes, and opened on the back. The collection in this case may be part only of a large psoas abscess, some of the pus gravitating backward in consequence of long confinement of the patient in the recumbent position. Dorsal abscess usually first appears on one side of the spine, its inner margin being often not more than an inch or two from the vertebral column. The pus occasionally passes outward along the intercostal muscles, and points in the lateral region of the thorax or abdomen, or near the middle line in front.

Dorsal abscess is frequently mistaken for fatty tumor, chiefly on account of its smooth outline and the absence of inflammatory symptoms. Besides, this is a favorite situation for lipoma. The aspirating needle should be resorted to in all cases of doubt. From abscess, the result of a necrosed rib, and from a pointing empyema the diagnosis should be made with ease by due attention to the symptoms.

It is remarkable, considering the proximity of the pleural cavity, how seldom abscess, the result of caries of the thoracic vertebræ, encroaches on that cavity. Cases are reported, however, in which this cavity has become the receptacle for a dorsal abscess, and fatal pleurisy has resulted from this cause. Agnew[1] refers to a case in which, through inflammatory adhesion, the two layers of the pleura, with the lung, united to the sac of the abscess, and through ulceration the purulent accumulation opened into one of the bronchial tubes and was discharged by the mouth.

Psoas Abscess.—This is the commonest variety of abscess, resulting from vertebral disease. It may follow disease in any part of the dorsal or lumbar portions of the spine, but is most frequently met with in cases where the lower dorsal or upper lumbar regions are affected. The pus, guided by the thickened periosteum and soft parts, reaches the diaphragm, where it arches over the lumbar muscles, and forcing a passage beneath the internal arcuate ligament, enters the substance of the psoas magnus muscle, along which it passes to its insertion beneath Poupart's ligament, and presents in Scarpa's space. Thus the entire psoas sheath may become converted into a bag of pus, the muscle being removed by a process of absorption. Bifurcation of the abscess sac has been known to take place high up, the pus descending in both psoas muscles forming a double psoas abscess; or two abscesses may form independently at the source of the disease. The latter variety, however, is very rare.

The pus may leave the psoas sheath at any part in the course of the abscess, proceeding sometimes in odd directions. Thus it may pass forward and find its way along any of the planes of areolar tissue in the abdominal wall, travelling between the transversalis muscle and fascia, or, perforating the fascia, may get between the latter and the peritoneum. Again, taking a more superficial course it may point in front, perhaps in the position of the external abdominal ring, closely simulating inguinal hernia. Or a portion of the abscess may pass along the sacrum by the side of the rectum and present in the perineum, like an ischio-rectal abscess. Or, finally, leaving the pelvis by the great sacro-sciatic notch, either above or below the pyriformis muscle, it may appear in the gluteal region (gluteal abscess), and thence pass down the thigh in the course of the sciatic nerve. The small intestine, colon, rectum, and bladder have all been penetrated by the pus from psoas abscess. Broca[2] reports a rare form of psoas abscess where the pus entered the hip-joint, penetrating the anterior part of the capsule. In its passage through the iliac fossa it is not uncommon for a psoas abscess to be arrested in its progress and form a prominent swelling. It is then termed "iliac abscess."

Below Poupart's ligament a psoas abscess generally takes an independent course, either spreading over the front of the thigh, or, guided by the sartorius muscle and the fascia, passes down the inner aspect and back of the limb, until, as in a case reported by Erichsen,[3] it may reach even to the heel.

Diagnosis.—This is usually an easy task, providing always that a rigid investigation has been made regarding the condition of the spine. It is true, psoas abscess may make its appearance before any noticeable change has taken place in the contour of the spine, but there will be present, almost invariably, a feeling of stiffness of the back, and a persistent pain in one locality. As before intimated, it is possible to have suppuration within the sheath of the psoas muscle as the result of sprain or inflammation of the muscle itself (psoitis), quite independently of disease of the vertebræ. Here there will be an absence of all the ordinary signs of Pott's disease, and thorough evacuation of the abscess should be followed by speedy cure. The simple form is found most frequently in adults.

Among the conditions met with in the vicinity of Poupart's ligament, with which psoas abscess might be confounded, are the following: Large buboes or glandular abscesses, suppuration from hip-joint disease (in those cases where the bursa of the conjoined tendon of the psoas and iliacus muscles communicates directly with the hip-joint), hernia, serous cysts, fatty tumors, pus from an empyema which has found its way into the psoas sheath, aneurism, and phantom tumors in hysterical females. While the abscess is still in the iliac fossa there may be some difficulty in diagnosing it from peri-cæcal abscess (on the right side only), perinephritic abscess, fluctuating renal tumors, and iliac abscess, the result of disease of the sacro-iliac joint or of the pelvic bones. There is, besides, the possibility of an abdominal or iliac aneurism, communicating with the sheath of the psoas muscle and forming a diffuse, non-pulsating extravasation. The pain from erosion of the vertebræ in such a case may easily be mistaken for the pain of Pott's disease.

It would be impossible within the limits of this article to give the diagnostic differences between psoas abscess and all the conditions above enumerated. It is simply necessary to state that in the latter, almost without exception, there will be an absence of stiffness and pain in the dorsal and lumbar spine; whereas in none but abscess accompanying Pott's disease will there be any excurvation.

Lumbar Abscess.—This usually results from disease of the lumbar spine, although it is possible to have this variety of spinal abscess from disease in the dorsal region. Here the pus, whether it comes from a psoas abscess, or directly from caries of the lumbar vertebræ, passes to the outer edge of the quadratus lumborum muscle, and projects posteriorly in the space between the last rib and the crest of the ilium. Like all cold abscesses in the back, this may readily be mistaken for fatty tumor, but attention to the points referred to in connection with dorsal abscess should obviate the possibility of such a mistake.

General Observations. — Spinal abscess seldom makes its appearance for many months after the disease in the vertebræ has begun. In fact, many years have been known to elapse before suppuration was noticed. Such cases are probably examples of what Paget[4] terms "residual abscess," meaning an old abscess cavity, in which from some cause, as ill-health or injury, a fresh inflammation, and suppuration, have been suddenly lighted up. On the other hand, abscess may be the first indication of the presence of caries. As might be imagined, the more acute the disease in the bone, and the greater the constitutional disturbance, the more rapidly does abscess form and make its appearance on the surface. Again, we meet with cases where great excurvation has occurred without any evidence of suppuration.

Prognosis of Spinal Abscess.—The larger the abscess, and the more extensive the ground traversed by the pus, the more serious will be the prognosis. The most favorable cases are those in which the abscess opens close

to the seat of disease. The greatest of the primary dangers in connection with suppuration are exhaustion and septicæmia. Secondary dangers are inflammation of serous membranes, due to the invasion of cavities by the pus; hæmorrhage from ulceration into a large artery or vein; suffocation (in cervical abscess only), and amyloid disease of the liver and kidneys. Many of the deaths from Pott's disease occur soon after the abscess is opened. Thus Michel records a series of 28 cases where, in ten instances, death followed the evacuation of the abscess within twenty days. The presence or absence of hereditary predisposition to struma, the social conditions and hygienic surroundings of the patient, and the quality of surgical skill employed in the case, will be found to influence the prognosis in a marked degree.

TREATMENT OF SPINAL ABSCESS.—Up to a very recent date there was a general consensus of opinion among surgeons that spinal abscess should not be opened hastily. This advice should still be followed in cases where suppuration appears to be arrested, and absorption or caseation is likely to supervene. As a rule, however, where the collection is large, and evidently increasing, early interference is in order. Since Lister began to teach surgeons how to take care of these abscesses the old dread of interfering with them has ceased to exist.

Cervical Abscess.—Here, perhaps, more than in any other form, should the practice of early opening prevail, lest, bursting unexpectedly, the pus might be drawn into the larynx and produce suffocation.

Opening through the Mouth.—Should the abscess point in the pharynx more markedly than elsewhere, one often has no alternative but to evacuate it through the mouth, by means of a trocar or of a guarded bistoury. The patient should be placed in the sitting position, with the head thrown well forward. An anæsthetic is not usually required, excepting perhaps in the case of a very rebellious child. The mouth should be held open by means of some simple gag, which can be withdrawn simultaneously with the bistoury, so as not to interfere with the action of the palatal and pharyngeal muscles in their endeavor to project the pus forward. The forefinger of the left hand may be used to depress the tongue and push it backward, thus forcing the epiglottis to close. The incision should be made as nearly as possible in the middle line, and directly upward. When the abscess is pointing, the sharpened finger-nail of the surgeon may be employed to open it, instead of the bistoury. Some antiseptic mouth-wash, containing carbolic acid, iodine, or Condy's fluid, should be used freely as a gargle, as well as for injecting the abscess-cavity.

Opening in the Neck.—When the collection tends to point laterally it will usually first be detected behind the sterno-mastoid muscle, on a level with the angle of the jaw. Here, when practicable, cervical abscess should always be opened, chiefly because of the comparative ease with which it may be kept aseptic. Professor Chiene, of Edinburgh, was one of the first surgeons to advocate this method of treating post-pharyngeal abscess. He recommends a free incision through skin, superficial fascia, and platysma muscle, carried along the posterior border of the sterno-mastoid. Then a small opening is made through the deep fascia, into which a director is pushed onward until pus is reached. The deeper parts of the incision are opened up by means of dressing-forceps, after Hilton's method. A drainage-tube is then introduced, and throughout the strictest antiseptic precautions are taken. There can be no objection to the use of the aspirator here, as in any variety of spinal abscess, providing the purulent collection can be accurately located in the neck. When the abscess is undoubtedly due to caries, the head and neck should meanwhile be well supported, either by means of sand-bags or by a leather collar. The writer employed plaster-of-Paris in a memorable case[5] of caries of the upper cervical vertebræ, with post-pharyngeal abscess, in which the weight of the plaster caused partial dislocation of one of the diseased vertebræ and alarming asphyxia, with almost complete paralysis of sensation and motion. The patient died of exhaustion in about four weeks.

In all varieties of spinal abscess the bag of pus acts as a sort of splint to the crumbling vertebræ; hence, before removing the purulent collection by operation, means should be taken to provide a substitute of some kind for the support about to be withdrawn. Sayre's plaster dressing (with the jury-mast in cases of cervical and upper dorsal disease) will be found one of the most convenient methods for carrying out this indication.

Dorsal and Lumbar Abscess.—These need not be interfered with until they show signs of rapid enlargement. The aspirator should first be brought into requisition. The needle should not be thrust into the summit of the abscess, but introduced at a considerable distance from the border, so as to traverse an inch or two of healthy tissue before entering the abscess-cavity. In this way leakage and the admission of air are effectually prevented. A firm compress and bandage should afterward be applied over the situation of the empty abscess. Aspiration may be repeated three or four times, after which, if ineffectual, or if the needle becomes blocked with curdy matter, a free, dependent opening should be made and a large drain introduced. Every means should be adopted to keep the cavity aseptic. The late Mr. Callender's method of hyperdistention with weak carbolic or boracic solution may be practised with benefit here.

Psoas Abscess.—There can be no objection to one or two aspirations in this variety of abscess, although it is well not to evacuate the contents completely at one time, as alarming syncope has been known to follow the sudden removal of large collections of this kind, doubtless from disturbance of the circulation. Some pains should be taken to make the valvular puncture above referred to.

There are few surgical conditions in which Lister's antiseptic precautions are so urgently called for as in the treatment of psoas abscess by incision. It is a well-known fact that, by the older methods, death from exhaustion or septic troubles almost invariably followed the opening of this variety of abscess. Paget has declared that he could not recall to mind a single case of extensive psoas abscess in which recovery followed the older plans of treatment. Should the abscess have, unfortunately, opened before surgical aid has been sought, much may still be done by injecting a solution of chloride of zinc (one per cent.), or of bichloride of mercury (1 to 5,000), followed by injections of warm water.

Opening below Poupart's Ligament.—When the abscess points below Poupart's ligament, the incision may be made at the most dependent point, and simply large enough to admit a good-sized drainage-tube, every precaution being taken to prevent sepsis. The part should be thoroughly washed and shaved, and the spray or continuous irrigation employed while the wound remains uncovered. To encourage free drainage, the patient should be kept in a sitting position, or, where the condition will justify it, he may be allowed to move about for a short time each day.

Opening above Poupart's Ligament.—Where the abscess is still intra-abdominal it may with advantage be opened above the ligament. An incision is made as if for ligature of the external iliac artery. The abscess-sac being reached, it is opened by scratching through it with a director, followed by dressing-forceps. Lister, who was probably the first to practise this method, claims for it that the abscess-cavity is by so much shortened, while the risks of putrefaction are considerably lessened. In fact, in cases where the abscess has already extended below Poupart's ligament the method of incision above described may with advantage be employed.

Operation in the Loin.—Professor Chiene, of Edinburgh; Mr. Frederick Treves, of London; and Dr. Norman Chavasse, of Birmingham, recorded almost simultaneously the successful treatment of psoas abscess by incision in the loin. Dr. Chavasse[6] describes the operation as performed by him, briefly, as follows: "An incision is made immediately above the crest of the ilium, commencing at the edge of the erector spinæ muscle, and carried three or four inches transversely outward toward the anterior superior spine. The various structures are

divided, as in colotomy, till the quadratus lumborum muscle is reached. The forefinger should then be passed downward and forward on the iliacus muscle till the tense and distended psoas sheath is detected. A scalpel should then be carried along the finger and the abscess incised, the opening being enlarged by dressing-forceps. A drainage-tube should be introduced and the wound treated antiseptically." In this way the anterior surfaces of the bodies of all the lumbar and of the last dorsal vertebræ can be reached from the loin and thoroughly examined, while at the same time any particles of necrosed bone can be removed. The most dependent drainage possible is thus procured. Treves reports three cases treated in this way. In one he removed forty ounces of pus and a large sequestrum from the first lumbar vertebra. In another, where the abscess had pointed in the thigh, he passed a tube from the origin of the psoas muscle to its insertion, thus draining the entire abscess-cavity. The third case succumbed to amyloid disease soon after the operation.

Mr. Edmund Owen strongly advocates the early opening of psoas abscess. He recommends a free anterior as well as posterior opening, and a thorough washing out of the cavity. He says:[7] "The first opening I make close above the outer end of Poupart's ligament, using the scalpel until about an inch of the length of the fibres of the aponeurosis of the external oblique has been exposed. I then scratch through the fleshy attachment of the internal oblique and transversalis, and, keeping well below the level of the peritoneum, thrust the director into the swelling. Pus escapes, and the opening is enlarged by the dressing-forceps and the finger. A stiff probe is then passed through the abscess-cavity, and made to project beneath the skin on the outer side of the erector spinæ. With this as a guide, a counter-opening is made in the loin. The large cavity is then flushed perfectly clean with a warm antiseptic solution, and a drainage-tube of the size of a penholder is laid through the chasm for a few days, being afterward replaced by a silk thread." For a dressing Owen prefers pads of wood-wool and picked oakum inclosed in gauze bags. He irrigates with warm iodine-water decolorized by carbolic acid. He considers the sublimate solution highly dangerous, having had a sad experience in one case, where the use of a 1 to 1,000 solution caused the death, within four hours, of a child six years of age.

In conclusion, the writer would be disposed to urge the early and careful aspiration of psoas abscess, repeating this at least twice. Then, should a subsequent operation become necessary, he would be disposed to recommend Owen's method, above described, as being both safe and easy of execution. For purposes of irrigation the warm solution of boracic acid is preferred, being sufficiently antiseptic and free from toxic properties. As a dressing, a powder composed of equal parts of boracic acid and naphthalin or hydronaphthol may be dusted freely over the wounds and into the drainage-tube, the whole being enveloped in a large pad of sublimated jute.

SPINAL CORD, DIAGNOSIS OF LOCAL LESIONS IN THE. In diseases of the spinal cord it is usual for the lesion to involve a portion only of the organ. It is true that in general myelitis the entire spinal cord may finally become affected, but even in this disease it is the rule for the lesion to invade one part after another rather than for it to begin at once in the entire length of the cord. And it is well known that in infantile paralysis, in progressive muscular atrophy, in locomotor ataxia, in spastic paraplegia, and in ataxic paraplegia, the lesion is strictly defined in its extent, being limited so exactly to a set of nerve-cells, or of nerve-tracts of a single function, that for these affections the term "system-diseases" has been coined. Furthermore, from its peculiar form—that of a long but small organ—and from its location—within the spinal column—the spinal cord is liable to become the seat of disease at some particular level rather than in its entire length. Thus pressure from injuries of the vertebræ, or from the effects of Pott's disease, or by tumors; or destruction by wounds, or by intraspinal hæmorrhage, will affect only a small segment of the entire cylinder.

It is evident, therefore, that in diseases of the spinal cord local lesions are the rule, and that the symptoms will vary greatly, and will depend entirely upon the particular portion of the organ which is involved.

Hence, in the diagnosis of diseases of the spinal cord it is necessary to determine the situation of the lesion

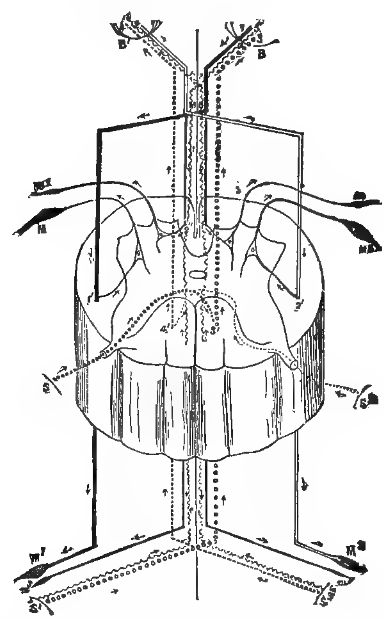

FIG. 3638.—Diagrammatic Representation of the Spinal Segment as a Spinal Centre and as a Conducting Medium. (Bramwell.) B, Right, B′, left, hemispheres of the brain; M O, medulla oblongata; 1, motor tract from right hemisphere: at M O it divides; the larger subdivision decussates, passes down the lateral column of the opposite side of the cord, and supplies the muscular fibres M and M′ on the left side of the body; at 1′ the supply to M is given off; the smaller subdivision does not decussate, but passes down the anterior column, and supplies the muscles m and m′ on the same (right) side of the body; 2, motor tract from left hemisphere; it supplies muscles M^2 and M^3 on the right side of the body, and muscles m^2 and m^3 on the left side of the body; S, S′, sensitive areas on the left side of the body; 3′, 3, the main sensory tract from the left side of the body; it passes into the gray matter of the segment, then decussates, and passes up the right half of the spinal cord in the posterior columns, and thence to the right hemisphere of the brain; S^2, S^3, sensitive areas on the right side of the body; 4′, 4, the main sensory tract from the right side of the body, up the left half of the cord to the left hemisphere of the brain; 5, 6, tract of muscular sense from the legs, passing up upon the same side of the spinal cord in which it enters, in the column of Goll, decussating at the medulla, above the motor decussation, that from the left side of the body (5) going to the right hemisphere, that from the right side (6) to the left hemisphere; the arrows indicate the direction of the nerve-currents.

producing the symptoms. And this is by no means as simple a matter as might be supposed. For the spinal cord is a long, cylindrical organ, made up of numerous segments, each of which not only has a function of its own, but also bears an important part in relation to the functions of other segments. Each segment of the cord consists of a mass of gray matter, surrounded by a series of white tracts, from which passes out a pair of spinal nerves. In some of the lowest order of vertebrata the comparative independence of each segment is indicated by the fact that the spinal cord consists of a series of bulbous enlargements joined together by only a few connecting fibres. And even in man there are some evi-

dences that the functions of each segment of the cord are independent of all others. But in the higher vertebrata the various segments are closely united to one another, and are also connected with the brain, which controls them all, by means of the white tracts surrounding the gray matter. Hence, in addition to its own special function as a nervous centre, each segment has functions of transmission of impulses to adjacent segments and to distant parts of the nervous system. Therefore, in dealing with local lesions in the spinal cord, the first point to determine is whether the lesion involves the nerve-centres of a single segment, or the tracts which pass through that segment to other centres. In the first case, when the gray matter of a single segment is affected, the symptoms are limited in extent and in number, consisting of localized paralysis, limited anæsthesia, loss of certain reflexes, disturbance of certain automatic actions, and local vaso-motor and trophic disturbances. In the second case, when the white matter of a single segment is affected, the symptoms are widespread and numerous, consisting of partial or complete paraplegia, anæsthesia of the lower half, or even of the entire body, loss of control over reflex and automatic activity, and extensive vascular and trophic changes. And when both gray and white matter of a single segment are totally involved, there will be a combination of local and general symptoms, the distribution and extent of which will depend wholly upon the particular level of the segment of the cord which is affected. It is therefore evident that the first step in the diagnosis of local lesions of the spinal cord is the determination of the functions of the various segments, and of the various tracts which pass through them.

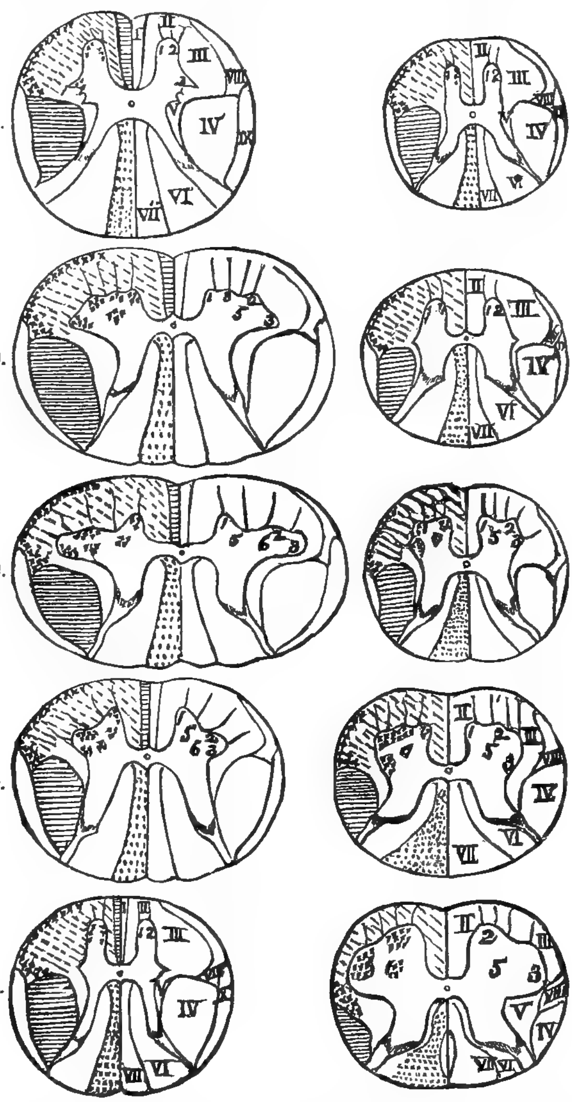

FIG. 3639.—Diagrams of Transverse Sections of the Spinal Cord at Different Levels; the level at each section is indicated by the number opposite to it. 1 to 6, Groups of cells in the anterior horns: 1, inner; 2, antero-lateral; 3, postero-lateral; 4, anterior; 5, median; 6, central. I to IX, Columns of the cord: I, Direct or anterior pyramidal tract, or column of Türck; II, anterior, and III, lateral ground-fibres, separated by exit of anterior nerve-roots; IV, crossed or lateral pyramidal tract; V, lateral limiting layer; VI, postero-external tract, or column of Burdach; VII, postero-internal tract, or column of Goll; VIII, antero-lateral ascending tract; IX, direct cerebellar column.

I. THE FUNCTIONS OF THE SEGMENTS OF THE SPINAL CORD.—Each segment of the spinal cord consists of that portion of the entire organ giving origin to one pair of spinal nerves (see Fig. 3638). There are, therefore, thirty-one segments in the human cord. There is no natural division between adjacent segments, but if a cord with its nerves be carefully removed, there will be no difficulty in cutting it up into segments, each of which will receive two afferent and give off two efferent nerves. Each segment is made up of two symmetrical halves, naturally separated by the anterior fissure and posterior septum, but joined by a commissure.

The afferent or sensory nerves enter the posterior surface of the segment, and, passing through the white matter, end in the gray. The efferent or motor nerves pass out from the anterior surface of the segment, having their origin in the anterior gray horn, and traversing the white matter bordering these horns.

A. The Gray Matter.—The size and shape of the area of gray matter, seen in horizontal section of the cord, differ in almost every segment, the difference between adjacent segments being more marked in the cervical and lumbar enlargements than in the dorsal region. The shape of the area of gray matter in the dorsal region resembles that of the letter H, and, accordingly, anatomists describe two lateral halves with a central gray commissure between them, and in each half an anterior and a posterior horn. In the enlargements of the cord the mass of the horns is much larger than in the dorsal region, and the shape varies in each segment. The amount of gray matter in any segment depends upon the number of cells in the anterior and posterior horns. These cells are not scattered irregularly through the gray matter, but are collected into groups. These groups are quite distinct in the anterior horns, in some cases being small, and only found in a single segment; in others being long, and extending through several segments. This varying arrangement of the anterior groups at different levels is seen in the figure (Fig. 3639, 1 to 6). The function of the cells in the anterior horn is to govern the motion and nutrition of the motor mechanisms of the body.

The more exact localization of motor functions in the groups of cells in the cervical and lumbar enlargements has been attempted by Ross and Spitzka. There are some of these groups, viz., the inner antero-lateral and postero-lateral groups (Fig. 3639, 1, 2, and 3), which develop early in fœtal life, and are common to man and the less highly developed vertebrates. These are thought to

govern the fundamental movements common to man and animals, and earliest acquired in children, viz., flexion and extension, abduction and adduction of the limbs. Other groups, viz., anterior and median groups (Fig. 3639, 4 and 5), are found only in monkeys and man, and the central groups (Fig. 3639, 6) in man alone. These are also found to develop later than the others. They are therefore thought to govern the accessory movements, which are more specialized and depend on finer adjustment, such as the act of walking upright, pronation and supination, and the finer motions of the hands and fingers, actions which are learned some months later than those of a fundamental kind. In some cases of disease, limited to these groups of cells, poliomyelitis anterior, the symptoms have been found to justify this distinction, loss of power and atrophy of certain muscles being produced by a lesion in certain groups of cells. The connection of the different groups, in various segments, with individual muscles, as far as at present known, is shown in the table accompanying this article.[1]

The arrangement of cells in the posterior horns is different from that in the anterior horns. There is a column of cells extending through the lower dorsal region, known as the vesicular column of Clarke, and situated in the median and inner part of the horn. The column begins in the third lumbar segment, and extends upward to the seventh dorsal segment. Its probable function is to regulate the vaso-motor and sympathetic nervous mechanisms.[2] There is a continuous column of cells in the middle of the posterior horn, not collected together into groups, but scattered through the neuroglia and gelatinous substance of the posterior horn. These cells are very small in size, and thus contrast markedly with those already described. It is probable that the gelatinous mass in the posterior horn has something to do with the sensory function, for it is present in the nervous system wherever a sensory nerve ends. The sensations of touch, temperature, and pain are carried into the posterior horns by the posterior nerve-roots, which terminate in these cells and the gelatinous substance.

All the cells of the gray matter give off branching processes which anastomose, forming a dense net-work of

Localization of the Functions of the Segments of the Spinal Cord.

Segment.	Muscles.	Reflex.	Sensation.
Second and third cervical..	Sterno-mastoid, trapezius. Scaleni and neck. Diaphragm.	Hypochondrium (?). Sudden inspiration, produced by sudden pressure beneath the lower border of ribs.	Back of head to vertex. Neck.
Fourth cervical............	Diaphragm. Deltoid. Biceps, coraco-brachialis. Supinator longus. Rhomboid. Supra- and infra-spinatus.	Pupil, fourth to seventh cervical. Dilatation of the pupil produced by irritation of neck.	Neck. Upper shoulder. Outer arm.
Fifth cervical	Deltoid. Biceps, coraco-brachialis. Brachialis anticus. Supinator longus. Supinator brevis. Deep muscles of shoulder-blade. Rhomboid, teres minor. Pectoralis (clavicular part). Serratus magnus.	Scapular, Fifth cervical to first dorsal. Irritation of skin over the scapula produces contraction of the scapular muscles. Supinator longus. Tapping its tendon in wrist produces flexion of forearm.	Back of shoulder and arm. Outer side of arm and forearm. Anterior upper two-thirds of arm.
Sixth cervical	Biceps, brachialis anticus. Pectoralis (clavicular part). Serratus magnus. Triceps. Extensors of wrist and fingers. Pronators.	Triceps. Fifth to sixth cervical. Tapping elbow tendon produces extension of forearm. Posterior wrist. Sixth to eighth cervical. Tapping tendons causes extension of hand.	Outer side of arm and forearm. Inside and front of forearm.
Seventh cervical..........	Triceps (long head). Extensors of wrist and fingers. Pronators of wrist. Flexors of wrist. Subscapular. Pectoralis (costal part). Latissimus dorsi. Teres major.	Anterior wrist. Seventh to eighth cervical. Tapping anterior tendon causes flexion of wrist. Palmar, seventh cervical to first dorsal. Stroking palm causes closure of fingers.	Inner and back of arm and forearm. Radial distribution in the hand.
Eighth cervical	Flexors of wrist and fingers. Intrinsic muscles of hand.		Forearm and hand; median and ulnar areas.
First Dorsal...............	Extensors of thumb. Intrinsic hand muscles. Thenar and hypothenar eminences.		Ulnar distribution to hand.
Second and twelfth dorsal..	Muscles of back and abdomen. Erectores spinæ.	Epigastric, fourth to seventh dorsal. Tickling mammary region causes retraction of the epigastrium. Abdominal, seventh to eleventh dorsal. Stroking side of abdomen causes retraction of belly.	Skin of chest and abdomen, in bands running around and downward, corresponding to spinal nerves. Upper gluteal region.
First lumbar	Ilio-psoas. Sartorius.	Cremasteric, first to third lumbar. Stroking inner thigh causes retraction of scrotum.	Skin over groin and front of scrotum.
Second lumbar	Ilio psoas, sartorius. Flexors of knee (Remak). Quadriceps femoris.	Patella tendon. Striking tendon causes extension of leg.	Outer side of thigh.
Third lumbar..............	Quadriceps femoris. Inner rotators of thigh. Abductors of thigh.	Bladder centre. Second to fourth lumbar.	Front of thigh.
Fourth lumbar	Abductors of thigh. Adductors of thigh. Flexors of knee (Ferrier). Tibialis anticus. Peroneus longus.	Rectal centre. Fourth lumbar to second sacral. Gluteal. Fourth to fifth lumbar. Stroking buttock causes dimpling in fold of buttock.	Inner side of thigh and leg to ankle. Inner side of foot.
Fifth lumbar..............	Outward rotators of thigh. Flexors of knee (Ferrier). Flexors of ankle, peronei. Extensors of toes.	Achilles tendon. Over-extension causes rapid flexion of ankle, called ankle clonos.	Lower gluteal region back of thigh. Leg and foot outer part.
First and second sacral....	Flexors of ankle. Long flexor of toes. Intrinsic muscles of foot.	Plantar. Tickling sole of foot causes flexion of toes and retraction of leg.	Leg and foot except inner side. Perineum and back of scrotum. Anus.

nerve-fibrillæ around the groups of cells. This net-work is supported by a trellis of neuroglia, and through it impulses pass in all directions, uniting the functions of the various cell-groups, and of the sensory and motor areas of the cord. It is probable that impulses coming to the segment, either from the periphery or from the brain, are not conveyed directly to the cells of the segment, but are distributed through the medium of this net-work of fibres to several groups of cells.

Furthermore, each segment controls in some degree the processes of nutrition in the part of the body with which its sensory nerves are connected. It regulates the vaso-motor tone in the organs and limbs, and it influences processes of growth and repair in the skin and mucous membranes. But the existence of trophic cells in the cord has not been proven. Nor can the automatic mechanisms of the cord be assigned to definite cells. They can only be referred to the gray matter of certain segments.

The function of the gray matter of the individual segments is shown in the preceding table. The facts upon which this table has been prepared are gathered from comparative anatomy, from physiological experiment, and from pathological observation. The level of the segment is given; the muscles governed by the groups of cells in it are mentioned so far as they are at present known; the reflex and automatic mechanisms governed by each segment are recorded, and the manner of producing the reflex acts; and the area of skin which sends its sensory nerves to the individual segments is described.

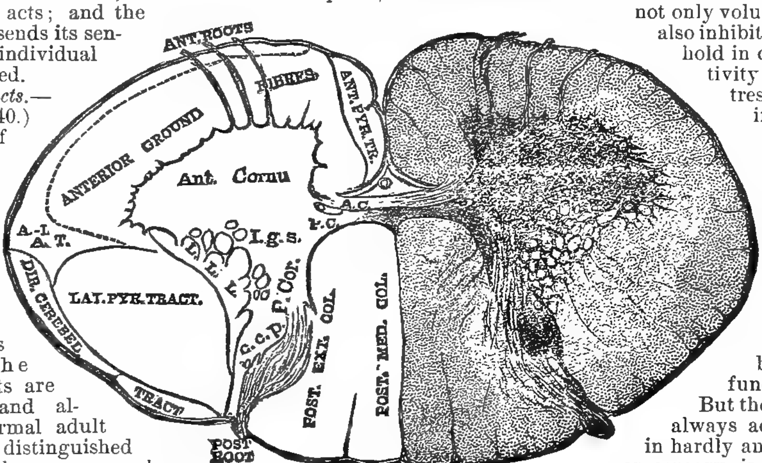

FIG. 3640.—(From Gowers.) Diagram of a Section of the Spinal Cord in the Cervical Region. A.C., Anterior commissure; P.C., posterior commissure; I.g.s., intermediate gray substance; P.Cor., posterior cornu; c.c.p., caput cornu, post.; L.L.L., lateral limiting layer; A.=L.A.T., antero-lateral ascending tract.

B. The White Tracts.—(Figs. 3639 and 3640.) The gray matter of the spinal segment is surrounded by white nerve-tracts, whose function is the transmission of impulses between adjacent and distant segments, and between the various segments and the brain. These tracts are quite numerous, and although in the normal adult cord they cannot be distinguished from one another, there are several means by which their limits are determined. Thus in fœtal cords of various ages different tracts can be distinguished, by the fact that they develop at different times. And in diseased cords pathological processes are often strictly confined to certain tracts. This is especially true of the processes known as secondary degenerations, by means of which the exact boundaries, the length, and the function of the various tracts have been ascertained. The older division of the columns of the cord into anterior, lateral, and posterior, must be set aside in favor of the later divisions founded on these facts.

In a cross-section of the cord at the cervical region the following tracts are seen in each half of the segment:

1. *The motor tracts*, two in number, which come through the anterior pyramids of the medulla, from the motor region of the cerebral cortex on either side of the fissure of Rolando. It will be remembered that the pyramids of the medulla decussate partially just at the upper limit of the spinal cord.[3] The majority of the fibres of each pyramid cross the median line to the lateral column of the spinal cord. The remainder pass directly onward into the anterior column. Those that cross over are called the crossed pyramidal tract. Those that do not cross are called the direct or anterior pyramidal tract, or column of Türck. The latter lies along the side of the anterior fissure of the cord, and is called the anterior median column (Fig. 3639, I). The former lies in a triangular space in the posterior part of lateral column, bounded by other tracts on all sides (Fig. 3639, IV). These motor tracts differ somewhat in size in different cords. When only a few fibres from the medulla cross over, the anterior median column is large and the opposite lateral pyramidal tract is small; but this is the exception. As a rule the lateral tract is three times the size of the anterior one. They differ also in length; for the anterior median column only extends to the mid-dorsal region, but the crossed pyramidal tract extends to the very lowest segment of the cord. They both send in their fibres to the anterior gray horns of the cord at all levels, and therefore decrease in size as they pass downward. They both transmit voluntary impulses from the brain to the anterior motor cells of the cord, a single nerve-fibre in the motor tract carrying an impulse which reaches several groups of cells through the fine net-work of fibres within the gray horn, in which it terminates. They both degenerate downward after any lesion which cuts them off from their nutrient cells in the cerebral cortex. If that lesion is in the brain on one side, the anterior median column on that side, and the crossed pyramidal tract on the opposite side, will be degenerated in the cord. If the lesion is in the cord on one side, both motor tracts on that side will degenerate downward. If the lesion divides the entire cord, the degeneration will be bilateral in both columns. These motor tracts transmit not only voluntary impulses, but also inhibitory impulses, which hold in check the reflex activity of the spinal centres. Hence a lesion in their course produces not only paralysis, but also a loss of control over the bladder and rectum, and an increase in the spinal reflex activity.

2. *The Association Tracts.* Each spinal segment has been shown to have functions of its own. But the different segments always act in harmony, and in hardly any act, either motor or sensory, is any segment independent of the rest. Hence a large part of the white matter of the cord is composed of tracts, shorter or longer, joining the various segments with one another, and associating their actions. These association tracts lie about the anterior horns of the cord, on their different sides, making up together a large antero-lateral column which has been divided artificially into an anterior column (Fig. 3639, II), and a general lateral column (Fig. 3639, III), the latter having a portion between the crossed pyramidal tract and the outer surface of the gray matter which has been called the lateral limiting layer (Fig. 3639, V). All these tracts are about the same size at all levels of the cord, thus differing from the motor tracts, which decrease in size from above downward, and from the sensory tracts, which increase in size from below upward. They degenerate but a short distance in any transverse lesion of the cord. It should not be forgotten that the anterior nerve-roots pass out of the cord through the anterior column, and that many of these roots pass upward or downward for some distance before making their exit. Hence this column is not wholly made up of association tracts. There is no form of disease limited to the association tracts exclusively, hence it is impossible to bring any known symptoms into connection with the lesion when they are affected in a general myelitis.

3. *The Sensory Tracts.* These occupy the posterior

columns of the cord, of which there are two on each side of the posterior median septum, viz., the postero-external column, or column of Burdach (Fig. 3639, VI), and the postero-median column, or column of Goll (Fig. 3639,

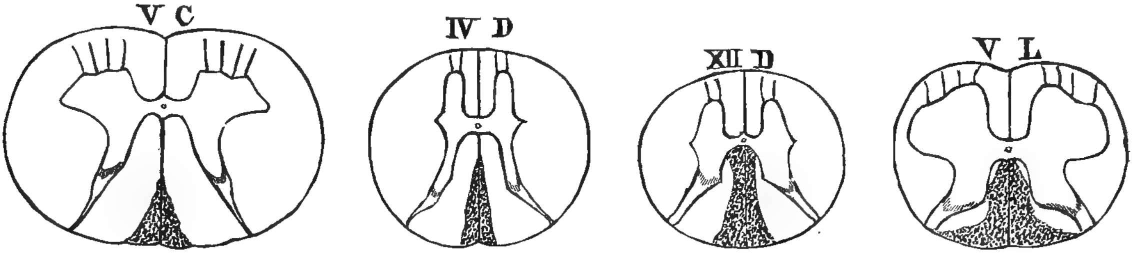

FIG. 3641.—Area of Ascending Degeneration after Compression of Cauda Equina, involving the Sciatic Nerve-roots only.

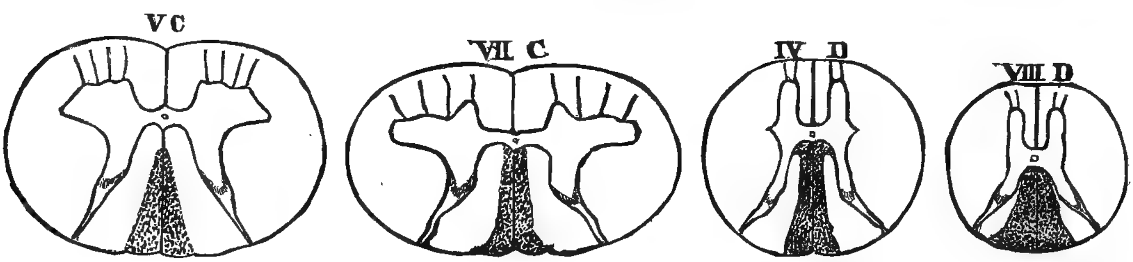
VII). The column of Burdach is made up very largely of the posterior nerve-roots which enter it and pass upward or downward for some distance before leaving it, to end in the posterior gray horn, or to enter the column of Goll. The column of Goll is made up wholly of long fibres extending from the posterior nerve-roots to the



medulla. The exact areas taken up respectively by the short posterior roots and the long fibres differ greatly at different levels, and they have only recently been determined by a study of the tracts degenerated after transverse lesions at different levels. These recent investigations deserve a moment's notice.

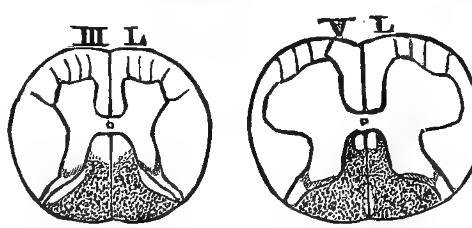


FIG. 3642.—Area of Ascending Degeneration after Compression of Cauda Equina, involving all the Sacral and Lumbar Nerves.

If the posterior nerve-roots are divided between the posterior spinal ganglia and their entrance into the cord, an ascending degeneration occurs in the cord. It is by observing the course of this ascending degeneration that the upward continuation of the sensory nerves has been determined.[4] The area of the posterior columns of the cord which degenerates upward differs in different cases. When the sciatic nerve-roots

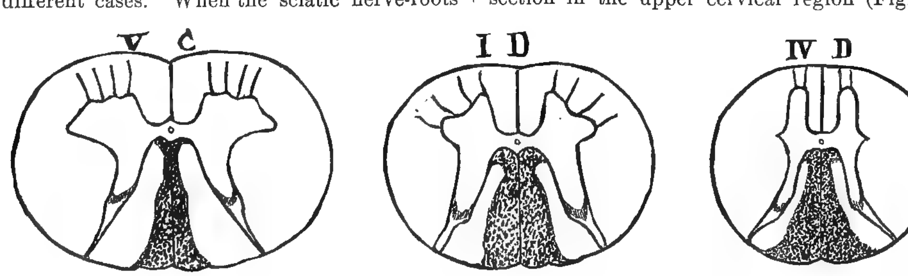

FIG. 3643.—Area of Ascending Degeneration after a Transverse Lesion of the Mid-dorsal Region.

alone are divided, or the sacral portion of the spinal cord is destroyed, the ascending degeneration occupies a large area of the posterior columns in the lumbar region, a smaller area in the dorsal region lying wholly in the column of Goll, and the posterior median portion only of the column of Goll in the upper dorsal and cervical regions (see Fig. 3641). When all the nerve-roots of the cauda equina, including both sacral and lumbar nerves, are compressed and destroyed, the ascending degeneration occupies a somewhat larger area than in the first case, involving both posterior columns as high as the middle of the dorsal region and a large part of the column of Goll in the cervical region (see Fig. 3642). When a transverse lesion of the cord in the dorsal region cuts off all sensory conduction from below the level of the mid-dorsal region, the area of ascending degeneration is still larger than in the first two cases, and in the cervical region involves the entire column of Goll (see Fig. 3643). When the cord is divided in the lower part of the cervical enlargement, the ascending degeneration involves a very large area, including both the entire column of Goll and a part of the column of Burdach in the upper cervical region (see Fig. 3644).

From these facts it becomes evident that the posterior nerve-roots contain a number of fibres which, after entering the cord, turn upward and pass on to the medulla oblongata, each successive set from below upward lying a little in front of, and outside of, the preceding set, and gradually filling out the entire column of Goll and a portion of the column of Burdach. In a cross-section in the upper cervical region (Fig. 3640) it can, therefore, be affirmed that the fibres in the posterior median part of the column of Goll transmit sensory impulses from the legs; that the fibres in the median and lateral portion of the column of Goll transmit sensations from the thighs and pelvis; that the fibres in the anterior portion of the column of Goll transmit sensations from the body exclusive of the arms; and that the median part of

the column of Burdach transmits sensations from the arms. Experimentation on animals has proven that the nerve-fibres entering the cord in the posterior nerve-roots, and passing upward in this manner to the medulla, degenerate upward upon the side on which they enter. There is no reason, therefore, to believe that in man there is any decussation in the spinal cord of the fibres thus far described. But since all sensations, except those of muscular sense, are known to cross over to, and ascend in, the opposite side of the cord in man, immediately after their entrance, it follows that the fibres thus far considered have for their function to transmit the sensations of muscular sense. And this conclusion is further established from the facts gathered from the pathology of locomotor ataxia. For in this disease, in which the muscular sense is the one most seriously impaired, the same areas of degeneration are found. There is, first, the primary sclerosis in the column of Burdach, involving the nerve-roots in it, and secondly, the secondary degeneration in the column of Goll, whose extent is determined by the extent of the primary lesion. The higher the primary lesion advances, the greater the area of the column of Goll involved. Since cases have been observed in which the sensations of touch, of pain, and temperature, and of the muscular sense, have been affected singly, it follows that the tracts conveying these sensations must be separate from one another. The fibres so far described terminate in the nuclei of Goll and Burdach. But from these nuclei the fibres of the interolivary tract and lemniscus arise, which are known to decussate in the sensory decussation of the medulla, and are known to transmit sensations of muscular sense exclusively. Hence the conclusion seems warranted that the sensory tract for muscular sense lies in the column of Goll for all parts below the arms, and in the median part of the column of Burdach for the arms.

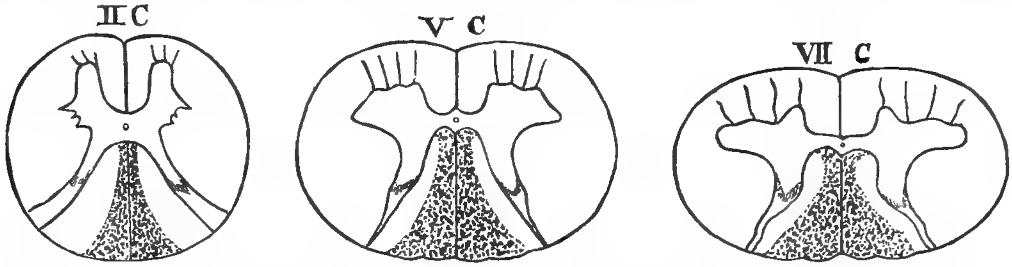

Fig. 3644.—Area of Ascending Degeneration when the Lower Cervical Region of the Cord is involved by a Transverse Lesion.

With regard to the sensory tracts for touch, pain, and temperature, our knowledge is much more indefinite. These sensations enter the cord by the posterior nerve-roots. But these roots do not send all of their fibres upward in the path already described. And if the area of the cord occupied by the column of Goll in the cervical region be compared with the entire area of the posterior nerve-roots, it will be seen that a mere fraction of the fibres entering the cord by these roots ascends to the medulla. The large remainder terminate in the cord. Anatomists describe various manners of termination. Some fibres end directly in the posterior gray horn; others pass through it to reach the anterior gray horn; others still, cross over through the posterior gray decussation to the other side of the cord. Many fibres enter the column of Burdach and pass directly through it to enter the gray matter in the vicinity of the vesicular column of Clarke; others ascend some distance in the column of Burdach before they enter the gray matter, and a few turn downward in the column of Burdach before ending in the gray matter. From the fact that general myelitis involving the posterior gray matter is always attended by sensory symptoms, it is concluded that many sensations are sent to the cells of the posterior horns. From the posterior gray matter nerve-fibres pass backward into the columns of Goll and Burdach, and mingle with the fibres of those columns, presumably ascending with them to the medulla. It is not improbable that these fibres transmit sensations of touch. Even in the most extreme cases of secondary ascending degeneration in the posterior columns, after division of the nerve-roots, many fibres in those columns escape. It is therefore possible that some of the fibres making them up have their origin and nutrient cells in the gray matter of the posterior horns, rather than in the posterior spinal ganglia. Hence the facts do not exclude the possibility of the transmission upward of sensations of touch in the posterior columns of the cord after such sensations have crossed the median line in the gray matter. And that they are transmitted in this region the older physiological experiments established. Other physiological experiments point to a transmission of sensations of touch in the lateral columns of the cord. And Gowers has established the existence of a tract in the periphery of the antero-lateral column (Fig. 3639, VIII), lying anterior to the direct cerebellar tract, which degenerates upward after transverse lesions. This is called the antero-lateral ascending tract. Positive facts, however, do not yet warrant the statement that a sensory tract is to be found in man in the lateral columns. And the fact that in lateral sclerosis, and in amyotrophic lateral sclerosis, as well as in ataxic paraplegia and in Friedrich's form of locomotor ataxia, in all of which the lateral columns are extensively involved and the fibres passing to the antero-lateral column from the gray matter must be implicated, but in none of which sensory symptoms are present or severe, would seem to prove that in man sensations of touch are not transmitted in the lateral columns. It is evident, therefore, that sensations of touch are probably transmitted upward through the posterior columns of the cord, after crossing over at the level at which they enter, but that a definite limitation of the tract through which they pass is impossible.

The sensations of temperature and pain are uniformly preserved or lost together, hence it is concluded that they pass in the same tract. No definite position can be assigned as yet to that tract. In syringo-myelitis, in which the lesion is limited to the central gray matter of the spinal cord between the anterior and posterior horns, a loss of temperature and pain sensations in all parts below the level of the lesion has been observed, and it has been concluded that these sensations are transmitted by the gray matter. Gowers believes that they pass in his antero-lateral tract, but the conclusion rests upon too small a number of observations to be hastily adopted. Spitzka, from a single case, concludes that sensations of pain pass in a triangular area on the periphery of the posterior columns, at the junction of the columns of Goll and Burdach. But each of these views is open to objections, and facts are wanting to determine between them.

4. *The Direct Cerebellar Column.* The last column of the cord to be described is one lying upon the outer surface of the lateral column, and extending from the lower dorsal region to the corpus restiforme of the medulla, and thence to the cerebellum. Its termination in that organ has led to its name—the direct cerebellar tract. It is made up of fibres whose origin is in that column of cells lying in the median part of the posterior horn known as the vesicular column of Clarke. The cells are only found in the dorsal region, hence all the fibres in this tract come from the dorsal segments of the cord. They reach

the lateral periphery of the cord by passing diagonally through the lateral column. They are supposed to transmit sensations upward from the Clarke column of cells to the cerebellum, because they degenerate upward after a transverse lesion of the cord. The function of both the cells and the tract is uncertain. From recent investigations by Gaskell, however, it seems probable that the vesicular column of Clarke is connected with the vaso-motor and sympathetic nervous systems by means of very small nerve-fibres extending from the sympathetic ganglia into the cord. If so, the function of the direct cerebellar tract is to transmit those rather indefinite sensations from the viscera, or to act as a tract for unconscious sensations or motor impulses necessary in a central regulation of visceral and vascular action. The hypothesis that they convey muscular-sense sensations from the trunk is hardly warranted, since these must be of little importance in lower animals, who do not walk erect—in which animals, however, this column is well developed.

II. Symptoms Leading to the Diagnosis of Local Lesions.—Such being the functions of the various parts of the spinal cord, it remains to discuss the symptoms arising when various parts are diseased. And it will be as well to approach this subject from the side of the symptoms rather than of the lesion, since it is the object to determine the lesion in any case.

1. *Spinal Paralysis.*—The motor tract conveying voluntary impulses from the brain to the muscles consists of two elements: first, the cerebro-spinal element, and secondly, the spino-muscular element. Each element consists of a set of nerve-cells and their outgoing fibres, which not only transmit impulses from the cells but are nourished by them. The cells of the cerebro-spinal element lie in the cerebral cortex. Their fibres make up the motor tract through the brain and through the direct and crossed pyramidal tracts of the spinal cord.[5] These fibres terminate in the net-work of the anterior horns of the cord at various levels, some of them reaching its very lowest part. Any lesion in the cells of the cortex, or in the course of the fibres which cuts them off from those cells, results in the degeneration downward of the cerebro-spinal element to its termination in the motor cells of the spinal cord. The *first form of spinal paralysis* is due to a lesion at the spinal part of this cerebro-spinal element of the motor tract. If the cord is divided by a transverse lesion at any point, the function of this element of the motor tract is thereby suspended. As a result, voluntary motion is arrested in the parts below the lesion. If the lesion involves but one-half of the cord, it is the limbs on the side of the lesion which are paralyzed. If it involves the entire cord, both sides are paralyzed. The extent of the paralysis depends upon the level of the lesion; the higher the lesion the more extensive the paralysis. The degree of the paralysis will depend on the character of the lesion, slight compression of the cord at one point by a tumor, or a pachymeningitis, or a projecting vertebra being followed by some stiffness of movement and rigidity of the muscles, with weakness, rather than by absolute loss of power in the parts below the level of the pressure. The cerebro-spinal element of the motor tract also transmits the inhibitory impulses which continually keep the spinal reflex and automatic mechanisms in check. A lesion of this tract, therefore, produces not only weakness and paralysis, but also increase of the deep reflexes, and impairment of control over the bladder and rectum. The muscular action of the limbs being no longer controlled by the brain, is governed wholly by the centres in the spinal cord. These act in response to sensory impulses, or spontaneously, without check, and hence the preponderating strength of flexor over extensor muscles tends to produce a position of adduction and flexion of the limbs which are paralyzed, and a heightened muscular tone, with tendency to rigidity. The nutrition of the paralyzed muscles may suffer somewhat from disuse, and from the attendant vaso-motor paresis, but no rapid atrophy is noted when the cerebro-spinal element of the motor tract is alone involved. And it is also to be noted that the paralysis affects the entire limb or limbs, and not any special group of muscles. In these cases the electric contractility remains normal in the paralyzed limbs.

A typical example of this form of spinal paralysis is seen in compression of the spinal cord, below the lesion, and in lateral sclerosis or spastic paraplegia (*q.v.*).

The *second form of spinal paralysis* is due to a lesion in the spinal part of the second element of the motor tract, viz., the spino-muscular element. This consists of the cells of the anterior gray horns of the cord, and the anterior nerve-roots which pass out through the anterior columns of the cord. Destruction of the cells suspends both voluntary and reflex motor impulses to the muscles. The cells not only control the motion, but also the nutrition, of the nerves to which they give origin, and of the muscles to which these nerves go. Therefore destruction of the cells produces atrophy of the muscles with which they are connected. If the destruction is gradual, the atrophy is gradual, as in progressive muscular atrophy. If the destruction is rapid, the atrophy is rapid, as in infantile paralysis. The degree of the atrophy depends upon the degree of destruction of the group of cells which govern the particular muscle affected. If the group is wholly destroyed, the muscle becomes totally atrophied. In addition to paralysis with atrophy there is in the second form of spinal paralysis a change in the electric reaction of the paralyzed muscles. They lose their contractility to the faradic current, and alter their contractility to the galvanic current, responding in a sluggish manner, and to the positive more readily than to the negative pole. This is called the Reaction of Degeneration (*q.v.*).

The extent of the paralysis depends upon the extent of gray matter affected, and a reference to the table of the localization of functions already given will enable one to determine the effect of a lesion at any particular segment, or through a group of segments, of the spinal cord. A typical example of the second form of spinal paralysis is found in infantile paralysis or poliomyelitis anterior. The muscles in this disease are paralyzed, atrophied, exhibit the reaction of degeneration, and lose their reflex excitability. An entire limb is rarely affected, certain groups of muscles being usually paralyzed together, *e.g.*, the deltoid, biceps, brachialis anticus, and supinator longus (upper arm group); or the extensors of the wrist and hand muscles (lower arm group); or the glutei and thigh muscles, with the tibialis anticus (thigh group); or the posterior tibial and peroneal groups of the leg (leg group). The muscles affected are not those which are supplied by a single peripheral nerve—a fact which enables a diagnosis between a lesion in the spinal cord and a lesion in a peripheral nerve to be easily made—but those which act together to produce a definite physiological act.

The contrast between these two forms of spinal paralysis can be seen at a glance in the following table:

First Type of Spinal Paralysis.	Second Type of Spinal Paralysis.
Lesion in pyramidal tracts.	Lesion in anterior gray horns.
Paralysis usually on both sides equally, in legs, or in legs and arms, never in arms alone.	*Paralysis* may be limited to any single limb, and rarely affects both limbs equally.
All muscles are about equally affected. No muscles are entirely normal.	Certain groups of muscles only are affected. Others escape wholly.
Muscular tone is heightened.	Muscular tone is diminished.
Tendency to rigidity appears.	Muscles are relaxed.
Reflex excitability is increased.	Reflex excitability is lost.
Atrophy is absent, or is slight; and merely due to disuse, hence is gradual in progress. It affects the entire limb.	*Atrophy* is always present in the paralyzed muscles. It advances rapidly, and may become extreme.
Electric contractility is unchanged.	*Electric contractility* is changed. Reaction of degeneration is present within two weeks of the onset.
Vascular tone is diminished; cyanosis and œdema may occur.	*Vascular tone* is diminished, but œdema does not occur.
Paralyzed limb is cold, and sweat may be increased.	Paralyzed limb is cool, but sweat is not increased.
Trophic disturbances in the skin are not infrequent.	*Trophic disturbances* in the skin do not occur.
The control over the bladder and rectum may be diminished or lost.	The control over the bladder and rectum is not impaired.
Example: Spastic paraplegia.	Example: Infantile paralysis.

The *third type of spinal paralysis* is a combination of the first and second types. When a transverse lesion of the spinal cord entirely destroys a single segment, it produces paralysis of the first type in the parts below the level of the lesion by cutting off the tracts to those parts, and paralysis of the second type at the level of the lesion by destroying the gray motor cells at that level. The general effect of such a lesion depends entirely upon the level at which it occurs; the higher the lesion, the greater the extent of the first type of paralysis. The distribution of the second type will depend on the level of the segment involved. The greater the extent of the lesion at the level affected, the greater the extent of the second type of paralysis. An example of this is also found in amyotrophic lateral sclerosis. When a longitudinal lesion of great extent occurs—such as the general destruction of the cord in general myelitis—the second type of paralysis is the form which is found, but all the muscles are affected, not merely a few groups. The bladder and rectum are also affected, and bed-sores are frequent.

In any case of spinal paralysis, if the electric condition of the muscles paralyzed be ascertained by the aid of a faradic battery, and the diagnostic points here brought together be applied, reference to the table of the localization of functions will enable the exact level of the lesion to be determined.

SPINAL ANÆSTHESIA.—The course of the sensory tract in the spinal cord is still somewhat imperfectly understood. It is known that all sensory impulses reach the spinal cord through the posterior nerve-roots, which partly enter the apex of the posterior horn, and partly enter the column of Burdach, and pass upward as already described. The sensations of muscular sense ascend on the same side as that on which they enter. Those of touch, temperature, and pain cross over as soon as they enter to the opposite side and ascend in it. The various views regarding the tracts transmitting these sensations have been already stated.

In transverse lesions of the spinal cord the area of anæsthesia present in the skin depends upon the level of the lesion. Anæsthesia of the feet, legs, and thighs, excepting their inner surfaces, indicates a lesion in the sacral and lower lumbar enlargement. Anæsthesia of the entire surface of the legs, thighs, and buttocks, including the genitals, indicates a lesion involving the entire lumbar enlargement. Anæsthesia around the body, attended by the so-called "girdle sensation," as if a band were drawn around the trunk, indicates a lesion in the dorsal region of the cord, and its level is indicated by observing the exact nerve above which sensation is normal. Anæsthesia of the trunk, and of the inner surface of the arms and one-half the hands, indicates a lesion of the lower portion of the cervical enlargement, not higher than the seventh cervical segment. Anæsthesia of the trunk and entire hand, forearm, and arm—the neck, upper chest, and outer surface of the shoulder only escaping—indicates a lesion as high as the fifth cervical segment. Transverse lesions higher than this cause sudden death from paralysis of the phrenic nerves. Limited areas of anæsthesia in the skin, at any part of the body, are to be ascribed rather to lesions in the peripheral nerves or nerve-roots (as in tumors of the cord) than to any local lesions in the cord itself; for posterior poliomyelitis as a distinct lesion is unknown. The areas of the skin which are connected with the various segments have been described already in the table. When a transverse lesion involves but one-half of the spinal cord, the anæsthesia is found upon the side opposite to the lesion, below the level of the lesion, and extends around the trunk in a band at the level of the lesion, the width of the anæsthetic band depending upon the longitudinal extent of the lesion. On the side of the lesion below the level of the anæsthetic band the skin is hypersensitive to touch. Such unilateral lesions produce a loss of muscular sense on the hyperæsthetic and paralyzed side, not upon the side of the anæsthesia—a fact which proves that the sensations of muscular sense do not decussate within the cord.

Hyperæsthesia sometimes occurs from spinal lesions, but is quite rare. It indicates an irritation of the sensory tracts in the cord by hyperæmia, or by pressure, rather than destruction of those tracts. Gowers suggests that this hyperæsthesia may be due to an increased irritability of the part of the cerebral cortex to which the injured tracts pass, as well as to an intensification of the impression passing in them. *Pain* is a rare symptom in spinal-cord disease, excepting in locomotor ataxia. And here it is to be ascribed to irritation of the posterior nerve-roots within the cord, similar in character to their irritation without the cord, as occurs in meningitis and in diseases of the vertebral column. *Numbness* is a frequently mentioned symptom of spinal-cord disease, and has some value in local diagnosis, as the area of the skin in which the numbness is felt depends upon the level of the cord affected. Hence, when the numbness is limited to certain parts, especially to the extremities, a reference to the table will indicate the segment of the cord which is diseased. Thus in locomotor ataxia the beginning of numbness or pain in the little fingers indicates that the disease has advanced up the spinal cord and has reached the first dorsal and lowest cervical segments.

SPINAL ATAXIA.—This symptom always indicates an affection of the posterior nerve-roots in their passage through the column of Burdach. Inco-ordination is due to an interference with the reception of sensations of muscular sense which are sent in from the skin, joints, and muscles. These sensations may be intercepted as they pass through the nerves, for ataxia is a symptom of toxic multiple neuritis; they may be intercepted as they pass through the column of Burdach, as is the case in locomotor ataxia; they may be intercepted in the brain by lesions in the lemniscus (see Pons) or in the cerebellum (see Cerebellum). It is probable that a portion of the muscular sensations are sent to the gray matter of the cord, producing reflex action of balancing, and unconscious co-ordination, and that the remainder are sent upward to the brain. For the inco-ordination in cerebral disease, when the latter only are disturbed, is less severe and intense than in spinal-cord disease, where all are implicated. Ataxia from neuritis is usually accompanied by tenderness in the nerves and muscles. Ataxia from cerebellar disease is only present in the act of walking, and is attended by vertigo. Ataxia from spinal disease is not attended by these two symptoms, but is usually accompanied by severe lightning pains and by loss of deep reflexes, together with other characteristic symptoms of locomotor ataxia (*q.v.*).

It must be stated here that in lesions of the spinal cord, as in those of the nerves, the motor symptoms are usually more pronounced than the sensory symptoms; and even when the spinal cord is greatly compressed, or disintegrated, sensory impulses may continue to pass after motor impulses are entirely arrested.

DISTURBANCES OF THE SPINAL REFLEX AND AUTOMATIC ACTION.—Whatever view may be held regarding the nature of spinal reflex action, it is well established that certain structures are necessary to its production. It is necessary that a sensory nerve from the surface of the body be capable of transmitting impulses to the spinal cord. It is known that the fibres transmitting the centripetal impulses from the skin enter the apex of the posterior horn, while those transmitting impulses from the tendons enter the median surface of the posterior gray matter after traversing the lateral part of the column of Burdach called the root zone. It is also necessary that the net-work of nerve-fibres through which impulses pass from the posterior gray matter to the cells of the anterior horn be intact. It is also necessary that the groups of cells in the anterior horn, and the motor nerves from them to the muscles, be in a normal state, or capable of exercising their functions. These structures, together, make up a reflex arc, and a lesion in any part of this arc will arrest the reflex activity. Thus neuritis, outside the cord or due to meningitis, may interfere with the conduction of impulses to and from the cord; posterior sclerosis may arrest centripetal impulses as they reach the root zone; general myelitis may destroy the net-work of fibres within the gray matter; and anterior poliomyelitis may

destroy the motor cells in the anterior horn. All these diseases, therefore, may cause a loss of tendon reflex. There are reflex activities governed by almost every segment of the cord, as may be seen in the table ; and the particular reflex which is suspended in disease will depend wholly on the location of the lesion. Hence the loss of any one or more reflexes gives important information as to the seat of the lesion. And this can be ascertained after examination of the patient by a reference to the table. It has been already stated that an inhibitory influence is exerted by the brain upon spinal activity, and that this influence is conducted to the spinal motor cells through the motor tracts in the lateral column. Anything which impairs the conduction of impulses through this tract will result in removing restraint from the spinal reflexes and allowing them full sway. Hence an increase in deep spinal reflexes indicates a suspension of function in the lateral pyramidal tracts. A transverse myelitis, therefore, will cause an increase of the reflexes below the level of the lesion, and a loss of the spinal reflex governed at the level of the lesion. This has been already mentioned in connection with spinal paralysis. The skin reflexes are, however, not increased by lesions in the pyramidal tract.

The automatic activity of the cord includes the mechanisms of micturition and defecation. These mechanisms are complex reflexes, several sensory impulses combining to produce a compound motor effect, a part of which is inhibitory and a part of which is active. Thus in micturition, the sensations of pressure on the sensitive neck of the bladder, and of distention of the entire organ, produce an inhibition of the motor impulses which normally hold the sphincter tight, and set in activity the motor impulses which contract the detrusor urinæ, thus emptying the bladder. The same is true, *mutatis mutandis,* of the other automatic acts. The structures necessary for any one of these acts are similar to those underlying the simple spinal reflex, and the same lesions arresting it may arrest these acts. But the result of such arrest is more serious, for, in the case of the bladder or rectum, retention or passive incontinence of urine or fæces may follow. And if the inhibitory impulses from the brain to these centres are cut off, the voluntary control over these mechanisms is impaired, and the acts cannot be initiated voluntarily, and active incontinence may result. The location of the rectal mechanism is in the lower sacral region. That of the bladder and sexual mechanisms is in the mid-lumbar region. Hence, when these parts are the seat of a lesion, or are cut off from the brain by a lesion at a higher level in the motor tract, incontinence, either active or passive, or retention, may result.

A part of the automatic mechanism of respiration is governed by the cervical and dorsal regions of the cord, and is interfered with in disease in those regions. Lesions of the upper cervical region paralyze the diaphragm and thus cause death.

Disturbance of vaso-motor and trophic functions of the cord may occur from various forms of lesion. Anterior poliomyelitis produces atrophy of the muscles paralyzed, and a sufficient affection of the vaso-motor system to cause objective, as well as subjective, coldness in the limb ; and when the lesion lies deep in the anterior horn, an arrest of development of the bones of the limb affected. General myelitis is usually associated with a tendency to bed-sores upon the parts exposed to pressure, which cannot be avoided by the most scrupulous cleanliness, and to cystitis, and these are ascribed to a disturbance of trophic impulses to the skin and bladder. Posterior sclerosis is sometimes associated with trophic changes, such as perforating ulcers, joint affections (Charcot's arthropathies), and eruptions on the skin. In a few cases of leprosy serious lesions of the posterior gray horns have been observed. In general myelitis there is a partial vaso-motor paralysis, indicated by cyanosis, sluggish circulation, œdema, and coldness, with abnormal sweating in the paralyzed parts. But any definite statement regarding the exact localization of vaso-motor or trophic functions in the spinal cord cannot be made as yet. And recently many vaso-motor and trophic symptoms, formerly supposed to be due to spinal lesions, have been found to be produced by disease in the peripheral nerves. It is, however, established that trophic lesions are most frequently observed when the gray matter of the spinal cord in the vicinity of the central canal, including the vesicular column of Clarke, is the part diseased ; or when all sensation is cut off from the paralyzed limbs by a transverse lesion.

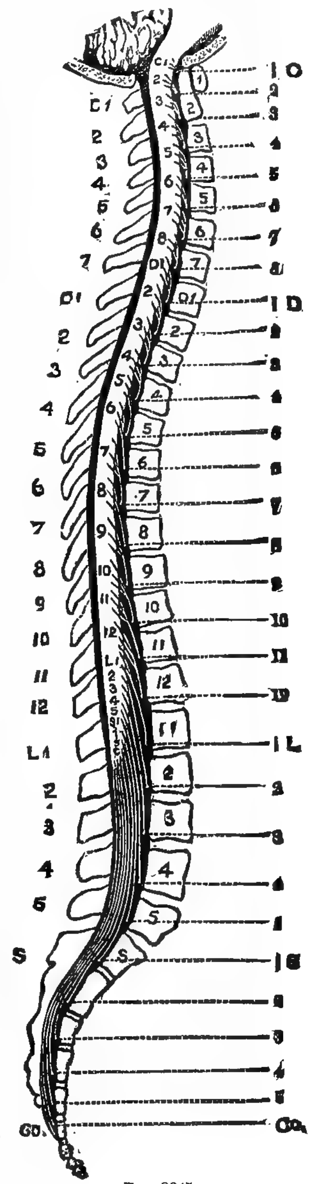

Fig. 3645.

The regulation of urinary excretion is presided over by a centre in the medulla, and the nerve-tract thence to the liver and kidneys is traced through the cervical region of the spinal cord to the first dorsal segment, where it enters the sympathetic chain of ganglia. A lesion in the lateral column of the cervical cord, by involving this tract, may cause a vaso-motor paralysis of either the liver or the kidneys. In the former case diabetes mellitus is produced ; in the latter, diabetes insipidus results. It is therefore necessary, in lesions of the spinal cord, to examine the amount and constituents of the urine.

In any case of spinal disease where it is desirable to localize accurately the lesion, it is suggested that a written summary of the symptoms be compared with the table of localization of the functions of the cord, when it will become evident, by contrasting the normal with the abnormal conditions, what part of the cord is affected. As Bramwell justly observes, "the essence of the clinical examination of the spinal cord consists in the systematic and separate examination of each spinal segment, by observing the motor, sensory, reflex, vaso-motor, and trophic conditions of its body area." Such an examination will lead to accurate diagnosis of local lesions.

But one point remains to be mentioned, that is, the relation of the various segments of the cord to the bodies and spines of the various vertebræ. As the cord extends only to the level of the second lumbar vertebra, its various segments do not lie opposite to the vertebræ from which they are named. The accompanying diagram of Gowers displays the mutual relation between the segments and their nerves, and the bodies of the vertebræ, and no further description is needed.

SPINAL CORD DISEASES. General Symptomatology and Diagnosis.—The spinal cord is a conductor of outgoing impulses, which are: 1, motor, to muscles; 2, secretory, to glands; 3, vaso-motor, to blood-vessels; 4, trophic, to skin, muscles, bones.

It conducts ingoing impulses, causing: 1, general sensations—cutaneous, articular, muscular, and visceral; 2, special sensations—tactile, thermic, and muscular; 3, exciting reflex actions, simple and complex, and arousing automatic centres.

The cord contains arrangements of cells forming reflex and automatic centres.

These are the vesical centre, the anal, sexual, uterine, subordinate sweat and vaso-motor centres, cilio-spinal centres, and centres which regulate in a measure the functions of the abdominal viscera and the development of heat.

The symptoms produced by disease of the spinal cord are due to interference with these various functions, and a thorough knowledge of the anatomy and physiology of this organ is the best means of guiding one to their interpretation. Those which may be called the dominant, and, in a measure, characteristic symptoms of spinal cord disease are the following, it being remembered that we have not only the individual symptoms to study, but their distribution and clinical history, in order to learn that they are peculiar to an organ or a disease.

I. Of the motor class we have, in diseases of the spinal cord peculiar paralyses and spasms. These are either bilateral and paraplegic, as is usually the case in adults, or monoplegic and unequally distributed, as is often the case in children. Spinal paralyses are very rarely indeed hemiplegic, and they, of course, never involve the face. They are accompanied with wasting and sensory disorders, and involvement of the organic spinal centres. By these signs we can thus readily distinguish spinal from cerebral paralyses in almost all cases. Paralysis that occurs from involvement of the nerves is usually more circumscribed, and if widespread, as in multiple neuritis, is painful, with the sphincters, vesical and rectal, only very exceptionally involved. Spasm is rare in the paralysis from neuritis, but frequent in that from spinal and cerebral disease.

In general, a paralysis with atrophy and without pain, or one with spasm and pains, means an involvement of the cord; a paralysis with pain and wasting means involvement of the nerves; a paralysis with spasm, but without wasting or much sensory disturbance, means involvement of the brain.

Excessive motor action (hyperkinesis) without paralysis is a somewhat rare condition in spinal cord disease. Spinal convulsions, however, occur in tetanus and as the result of some poisons; while in the spasmodic disorders known as writers' cramp and chorea, the cord is in part involved.

The peculiar electrical reactions in different forms of paralysis are of great help in determining the seat of the disease (see special articles).

II. The pains due to spinal cord disease are somewhat characteristic. They are usually darting in character, and radiate through a number of branches of outgoing nerves; or they are cinctural, causing a feeling as if the trunk were squeezed in a vise. Band-like feelings also occur about the head and lower limbs. Pain and tenderness along the spine occur in spinal irritation, in meningitis, and acute myelitis, but are rare in chronic diseases of the cord. The tissue of the spinal cord is probably somewhat sensitive to painful irritations in the posterior and antero-lateral parts, but practically most spinal pains come from irritation of the posterior roots, or root zones. Anæsthesia rarely follows organic cerebral disease, and it is then unilateral; therefore, when present in any other form of distribution, it is usually a symptom of involvement of the medulla, cord, or nerves. If the lesion is in the cord, the anæsthetic region is most likely to be diffuse and bilateral, and to be limited at a certain level of the limb or trunk. Delayed sensation and allocheiria, or transferred sensation, are usually evidence of cord disease. Parasthesiæ, and in particular burning sensations, are, as a rule, due to neuritis, while a peculiar sense of heaviness, often complained of, is of spinal origin. Ataxia due to disturbance of muscular and articular sensibility used to be thought a sign of disease of the spinal cord, and such is usually the case. But ataxia may occur in neuritis.

It will be seen that the extent and location of sensory symptoms determine the question of spinal or peripheral origin more than the character.

III. In certain spinal affections involving the central gray, such as syringomyelia and progressive muscular atrophy, there are decided disturbances of the vaso-motor system and of the sweat-glands. The involvement is usually widespread and includes a whole limb, or nearly all of the bodily surface. Œdema, hyperidrosis, vaso-motor spasm, and paralysis, occur in a more localized and limited manner, from disease of nerves.

IV. It is quite impossible in many cases to say positively what neuro-trophic changes are due to spinal, and what to peripheral, neural influence.

However, the rule is that the profounder trophic disturbances, such as decubitus, symmetrical gangrene, osseous and articular lesions (arthropathies), scleroderma, and the severe forms of muscular atrophy, are of spinal origin. The more superficial lesions of the skin, such as herpes, glossy skin, etc., and minor degrees of muscular atrophy, are more likely to be peripheral. Muscular atrophies result from degenerative myositis, from neuritis, and from myelitis. For the special characters of the different forms the reader is referred to the articles on these subjects.

V. Among the common symptoms of cord disease are disturbances of the superficial, the deep, and the organic reflexes. The presence or absence of the superficial skin reflexes gives us very little practical information, as they are not abolished or exaggerated without other symptoms. In some cases a study of them may furnish a guide to the height of the cord lesion.

The deep, or tendon, reflexes are always present in healthy persons (the exceptions are not one per cent.). When exggerated, they indicate a great degree of cerebro-spinal irritability (hysteria, neurasthenia), or some cerebro-spinal lesion. Organic disease of the peripheral nerve may usually be excluded.

A loss of tendon reflexes, on the other hand, may be due either to peripheral nerve or spinal cord disease, but not to cerebral disease unless there is also paralysis. If the loss is not due simply to motor paralysis, the trouble may, in the majority of cases, be referred to the cord.

Disturbance of organic reflexes and centres of visceral control is a common, early, and almost pathognomonic sign of disease of the spinal cord. Some vesical weakness, or sexual weakness, may be for years the only sign of approaching degenerative changes. It is only in certain rare cases that the bladder and rectum become involved through inflammation of the nerves (multiple neuritis). In profound cerebral and mental disturbance, control over the organic centres may also be lost.

In diseases affecting the central gray of the cervico-dorsal segments of the cord, pupillary disturbances, retraction or bulging of the eyeball, and facial flushing, pallor, or sweating may occur.

The spinal cord contains thermogenetic centres in its

central gray, and an increase or lowering of bodily temperature from disease of these parts is sometimes observed. A lowering of temperature is especially noticeable in poliomyelitis anterior.

General Pathology.—The spinal cord is subject to nearly all the diseases which affect other tissues of the body. Owing, however, to its peculiarly guarded position, the nature of its tissue, and its vascular supply, it is much less often affected with fatal disease than most organs, and is practically exempt from all but a few types of pathological processes. (Among 2,456 deaths from nervous disease, not more than 50 can be attributed to the spinal cord, leaving out the acute meningitis of children.—"Rept. New York City Health Board.") These are acute and chronic inflammations and degenerations. But though organic disease is rare, the cord, being a highly organized tissue, is often subject to functional or nutritional disorders, and to secondary degeneration from brain disorder.

Blood-vessels.—The arteries of the cord are numerous, but are of small calibre, smaller considerably than the veins, and carry blood at a low pressure.

Embolism and thrombosis are very rare, so far as is known, owing to the tortuous course of the arteries, and the capaciousness of the veins. Endarteritis and atheroma are not rare as compared with other organs, but are much less frequent than in the brain. The arterial branches, after penetrating the cord, anastomose with each other but slightly; hence the plugging of a single branch tends to produce softening, as in the brain. But softening may, perhaps, be produced in another way. The small blood-vessels of the cord are richly supplied with vaso-motor nerves, which have a powerful influence over the calibre of the arteries. The result is that by reflex influence, or direct irritation, these arteries may be so tightly closed as to produce complete anæmia, with consequent softening, or they may be so completely paralyzed as to produce minute hæmorrhages and incipient inflammatory conditions. Such, at least, seems to be the mechanism of many cases of acute white softening, of transverse myelitis, and of acute poliomyelitis.

The anterior horns of the cord, which are particularly liable to this latter affection, are supplied each by a branch of the anterior median artery, and occlusion of this would cause suppression of nearly all motor function in one segment of the cord (Ziegler).

According to Stenon's experiments, a stoppage of arterial supply to the spinal cord affects first the gray matter, then the white, and lastly the nerves and muscles. It is evident, from both anatomical and physiological considerations, that the gray matter is most richly and sensitively supplied with blood.

The veins are also numerous, are larger in calibre than the arteries, and communicate with the very rich plexus lying outside the dura mater, which also receives returning blood from the vertebræ, bones, and tissues posterior to these. The spinal cord veins cannot be injected from these large spinal plexus, and passive congestion of the cordes, from obstruction to the general circulation, rarely occurs to such an extent as to cause symptoms.

The circulation of the cord and its functions as a centre are, so to speak, "segmental." The blood flows in, horizontally, through lateral branches of the intercostal, lumbar, or sacral arteries, and flows out through veins at about the same level. Hence it is that acute disorders, which depend so much upon the vascular disturbance, are focal or transverse.

Fibre Systems.—The conducting portions of the cord necessarily embrace long stretches of nerve-fibres, and these must exist in their whole continuity, if at all. If disease attacks one point, cutting off a strand, it extends slowly till it involves a large part of the fibres. Hence chronic diseases of the cord, involving the white matter, always eventually extend up or down the cord.

Regions of Least Resistance to Disease.—For some reason, which is not at present well understood, the upper part of the dorsal cord is particularly liable to be affected in subacute or acute diffuse inflammation. The posterior columns in their lower part are most susceptible to chronic degenerations. The cervical and lumbar enlargements are especially often attacked by the ischæmic softening known as acute anterior poliomyelitis. Of the gray matter, the anterior cornual cells are especially susceptible to slow degenerative atrophy. Hæmorrhages, tumors, syphilitic and tubercular growths, rarely attack the substance of the cord, but take their start in the meninges.

Infections.—The cord enjoys considerable immunity against infections, that of cerebro-spinal meningitis being the only one frequently attacking it. The virus of tetanus, rabies, and of leprosy also especially involve the cord. Syphilis rarely affects it with peculiar growths, but often predisposes it to chronic degenerative and inflammatory disorder. Tuberculosis of the cord is also very rare, and tumors of all kinds, occurring primarily, may be considered pathological curiosities.

Meningeal Disease.—The spinal meninges are subject somewhat frequently to chronic or subacute inflammation; but primary acute spinal meningitis is not very often seen, except as part of the infective cerebro-spinal disorder.

Trauma.—Traumatism causes hæmorrhages, inflammation, and softening, and may start up degenerative processes.

The list of general pathological disturbances of the spinal cord is as follows:

I. *Malformations.* — Myelocele, meningo-myelocele (spina bifida), meningocele, heteratopia, micromyelia, macromyelia, and duplication of cord.

II. *Vascular Disorders.*—Congestion and anæmia, endarteritis, hæmorrhage, aneurism, embolism and thrombosis, œdema.

III. *Syringomyelia.*

IV. *Inflammatory Disorders.*—Acute, subacute, and chronic myelitis, ischæmic and hæmorrhagic softening, acute and chronic meningitis, abscess of cord.

V. *Degenerative Processes of Cells.*—Simple atrophy, fatty degeneration.

Degenerative Processes of Fibres and Neuroglia.—(1) Gelatinous degeneration. (2) Gray degeneration, or sclerosis, primary and secondary.

VI. *Tuberculosis.*—(1) Miliary, without or with meningo-myelitis. (2) Solitary tubercle.

VII. *Syphilis.*—(1) Gummatous. (2) Meningo-myelitis.

VIII. *Tumors.*—Chiefly sarcomata, gliomata, and gummata.

IX. *Diseases of the Meninges.*—External meningitis, internal meningitis of dura, internal meningitis of pia, hæmorrhages, malformations, tumors.

I. Under the head of malformations, or agenetic disorders, should be mentioned a bioplasmic tendency which leads, under slight causes, or simply in the course of development, to degenerative changes of the proper tissue of the cord. An illustration of this is the cord in hereditary ataxia, which is often micro-myelic or deformed, as well as degenerated.

Syringomyelia is also usually associated with, or caused by, some congenital malformation.

Of other malformations meningo-myelocele is the one oftenest observed.

II. Hyperæmia of the cord, so great as to cause symptoms, occurs occasionally as the result of sexual excesses, over-exertion, the stoppage of fluxes, and possibly in the caisson disease. An hyperæmia, affecting especially the meninges, seems sometimes to remain after attacks of meningitis. Spinal hyperæmia, however, of a chronic character, is a doubtful pathological entity, and though the spinal circulation is believed to be sluggish, its course is not easily interfered with.

III. Spinal anæmia is a more real thing. Profuse hæmorrhages, and mechanical obstructions, such as thoracic and abdominal aneurisms, may cause an anæmic paraplegia. Reflex paralysis from intestinal or other visceral injuries is probably due to a spinal ischæmia. Injuries such as gunshot wounds have produced reflex paralyses of presumably similar origin. In general anæmia, when very pronounced, the spinal cord shows some evidence of depression or irritation, but hardly more than do other organs.

After exhausting fevers and depressing traumatisms a paraplegic condition sometimes occurs; it is attributed to spinal anæmia, but probably the condition is more often due to nutritive disturbance. Chronic spinal anæmia can hardly be placed as yet in the category of distinct spinal affections.

Embolism of the spinal cord has been known to occur, but only very rarely. Thrombosis is still more infrequent. Miliary aneurisms, such as develop in the cerebral vessels, are sometimes found in the cord, but they do not, as in the brain, lead to spontaneous apoplexy.

IV. Inflammation is a peculiarly damaging process to the spinal cord; its nervous tissue, once destroyed, has no power of regeneration. Acute inflammation is usually accompanied at first with such exudation and congestion that function is completely and widely suspended. Later, when absorption takes place, the focus of disease becomes more circumscribed and the symptoms lessen. Hence, in acute and subacute myelitis, not ending fatally, the paralysis is usually retrogressive. This is especially the case in myelitis of the gray matter. Chronic inflammation has a tendency, on the other hand, to extend, either by a progress in the inflammation or by setting up secondary degenerations. Hence chronic myelitis causes usually a progressive paralysis. Acute myelitis, after improving, may develop into a chronic form, when we have first retrogressive, then progressive, paralysis. The characteristic changes in acute myelitis and meningitis will be described under the special headings. Inflammation of the spinal cord has this peculiarity, that it is usually necrotic and rarely leads to suppuration or abscess. The initial stage of acute myelitis is often an ischæmic or hæmorrhagic softening. In chronic myelitis the process affects the interstitial connective tissue primarily. As this increases in nutritive activity and anatomical extent, the nerve-fibres and cells atrophy.

V. In degenerative processes, however, the nerve-tissue suffers first, and then the interstitial proliferates. There is thus an inverse ratio in the activities of the two (Gowers). Primary degenerative processes attack, first, the long-fibre systems of the cord and the anterior cornua, throughout more or less of their extent. The primary degenerative process travels both up and down the strand, while secondary degenerations only travel in the direction in which the impulses are carried (Strümpell). Forel shows that in certain pathological conditions which cut the fibre off near its trophic cell, the degeneration extends up to this cell as well as along the peripheral part. After a degeneration is established in one strand, there is a tendency for it to extend to neighboring parts, through proliferation of the connective tissue. The term sclerosis has been used to indicate the condition in chronic myelitis, and also in primary and secondary degeneration. It is used as an equivalent also to gray degeneration. Gelatinous degeneration is a term applied to the earlier stages of the latter process.

VI. For details regarding the rarer conditions of tuberculosis and tumors of the cord, the reader is referred to the special articles. Syphilis appears powerfully to predispose the cord to chronic myelitis and degenerative disorders. The peculiar products of syphilitic development, such as gummata and diffuse gummatous inflammation, are rare. When present they attack, first, the meninges.

General Etiology.—The remarks made upon this head must bear chiefly upon the more common cord affections, viz., inflammations and degenerations. Acute inflammation of the anterior cornual gray matter (anterior poliomyelitis) is mainly confined to children, while acute transverse myelitis belongs to adults. Males suffer more from both forms. Exposure, over-exertion, injuries, and infective fevers furnish the prominent exciting causes. It is not unlikely that a specific infection is the active agent in the acute poliomyelitis or acute ischæmic softening of children. In chronic myelitis there is sometimes, though rarely, a hereditary tendency. Early and middle life, the male sex, syphilis, sexual excess, chronic alcoholism, occupations calling for exposure and over-exertion, are among the chief predisposing causes.

The causes which lead to chronic myelitis are much the same as those that lead to the typical degeneration disease, locomotor ataxia. In ataxia, however, the influence of a hereditary taint and of syphilis is more marked.

Syphilis and lead-poisoning seem to favor the development of chronic degenerations of the anterior horns (progressive muscular atrophy). Alcohol has less influence, pathologically, on the cord than on the peripheral nerves and brain, and it is a minor factor in causing its degenerations. Malaria rarely affects the cord, and then chiefly to produce vascular disturbances of the gray matter. Like alcohol, arsenic causes paralysis, if at all, by producing inflammations of the nerves. Chronic poisoning by ergot may lead to a sclerosis of the posterior columns. In lathyrismus the lateral columns are especially attacked. In certain forms of podagra both lateral and posterior columns degenerate (Tuczec). Hence certain poisons seem to pick out definite physiological tracts. Chronic disorders of the brain, particularly general paralysis, lead often to degenerative changes in the cord; and the brain undoubtedly holds a certain amount of trophic influence over the cord.

Traumatism is an important element in spinal pathology. Severe shocks and blows to the trunk may lead to hæmorrhage (usually meningeal), or excite a chronic myelitis, or lead to the development of degenerative processes. Still more often do traumatism and mental shock, combined, lead to nutritive or functional disorders. It is usually the case, however, in these instances, that the patient has some neuropathic predisposition. It is doubtful if purely mental shock can cause a spinal disorder, though it may lead to a neurasthenic or hysterical condition in which spinal symptoms predominate.

In conclusion, among the remaining causes of spinal cord disease are sudden disturbances of the circulation, such as hæmorrhoidal discharges, suppressed menses, infectious fevers, irritation and disease of peripheral organs.

General Therapeutics.—In the functional diseases of the spinal cord, such as spinal irritation, spinal exhaustion, and the various disturbances associated with hysteria or the morbid diatheses, treatment must always be more of a general than of a special character.

In the scleroses and degenerations specific attempts to affect the nutrition of the cord are attempted. Drugs, diet, rest, counter-irritants, electricity, and mechanical appliances are here used.

The posterior spinal nerves supply directly the skin of the back with sensation. They contain excito-reflex fibres, and by acting on them through the counter-irritants the circulation in the cord is profoundly affected.

The veins carrying blood from the cord join with those supplying the posterior spinal region, and unite with the intercostal, lumbar, etc., veins. By drawing blood from the tissues of the back, therefore, we presumably draw some away from the cord. Hence cupping the back is a favorite therapeutical measure. Slight changes in the spinal circulation are produced by posture, and this is of some importance. Faradic currents act on the cord by counter-irritation; galvanic currents, in addition, reach, and to some extent affect, the cord.

It may be considered certain that strychnia causes a hyperæmia of the cord in large doses; probably phosphorus does the same. Ergot can very probably cause some spinal anæmia, the bromides have a direct sedative power, and iodide of potassium has some resolvent properties here as in other organs. There is ground for believing that mercury has some antiphlogistic powers in acute spinal inflammatory disorders. It would not be worth while to discuss other drugs or remedies here. It will be seen that the spinal cord can be affected by the therapeutist, 1, through the posterior spinal and other excito-reflex nerves; 2, through the efferent blood-vessels; 3, through drugs that directly affect the circulation, the tissue irritability, and the nutrition.

The history of lathyrism, ergot-poisoning, and podagra leads one to hope that we may yet find that certain drugs especially affect certain parts of the cord.

Charles Loomis Dana.

SPINAL CORD DISEASES: ACUTE ANTERIOR POLIOMYELITIS. *Synonyms:* Acute inflammation of the gray anterior horns; acute atrophic spinal paralysis; infantile spinal paralysis; acute spinal paralysis of adults.

Definition.—The disease is characterized by a rapidly setting-in paralysis of various parts of the body, most commonly the lower extremities, preceded, especially in children, by a fever of short duration, sometimes by convulsions, coma, or other nervous symptoms. The paralysis, attended by flaccidity of the muscles, reaches its greatest intensity very quickly, and at the end of a few days begins to decrease. The permanently paralyzed muscles undergo rapid atrophy. In children, when the disease is extensive, there is arrest of development of the bones, and various deformities are produced.

The pathological basis appears to be an acute myelitis, affecting chiefly the anterior cornua.

The clinical appearances of the disease in children were pointed out by Heine in 1840, though its anatomical character was not recognized until a much later period. Since the report of cases by Meyer in 1868, it has been known that the disease occurs also in adults.

Etiology.—The disease occurs chiefly in childhood. According to some observers three-fourths of all cases occur between the ages of six months and two years. It is possible that the liability to disease in early life is due to the yet incompletely developed condition of the spinal cord, especially its motor portions. It occurs chiefly during the summer months. According to Sinkler, 77 of 149 cases appeared in July and August. Sex, heredity, and previous condition of health, seem to exert no influence. External injury, dentition, and exposure are often assigned as exciting causes, but their influence is, at least, doubtful.

The paralysis often appears after an attack of measles, scarlatina, or the like, so that in these cases—possibly this is true of other instances—the disease appears to be produced by a poison circulating in the blood.

Symptoms.—The disease presents a somewhat different appearance in children and in adults, so that it is well to describe each separately.

(a) *Acute Anterior Poliomyelitis of Childhood.*—The paralysis sometimes sets in suddenly, without any prior manifestations of disease; but, more commonly, it is preceded by high fever of a few hours' or days' duration, which may be complicated by various nervous symptoms, as somnolency, or even complete coma. In a large number of cases the disease is ushered in by convulsive seizures. These are like eclamptic attacks, and are of short duration. They may occur in large number, or there may be but a single seizure. The fever in these cases is, possibly, due to the acute inflammatory changes in the cord, but it is singular that such severe cerebral symptoms should usher in what appears to be a purely spinal disease.

The paralysis sets in very rapidly and soon reaches its greatest intensity. When the children are removed from bed, after subsidence of the fever, it is observed that the paralyzed parts hang lifeless, a condition which may at first be attributed to mere weakness. In older children, in whom such observations can more easily be made, the paralysis is usually observed to have come on overnight, or to have reached its height in a few hours, very rarely in several days, while every part affected is paralyzed at the same time.

The distribution of the paralysis is variable. Frequently a single limb, or only a group of muscles, is affected, but more commonly several members are attacked. The paralysis occurs most frequently in a paraplegic form, in the lower extremities, but it may attack the four extremities, and even the trunk, at the same time, or the upper extremities alone. More rarely it occurs in hemiplegic form, affecting a leg and arm of the same side, or even a leg on one side and an arm on the other. The paralyzed muscles are quite flaccid, so that the limbs can easily be moved in a passive manner; the reflexes, both superficial and deep, are abolished.

The paralysis reaches its height very quickly, and from that time the changes are only toward improvement, which takes place, to a greater or less extent, in all cases. The improvement is usually manifest within one or two weeks, and, for a time, progresses rapidly. In rare cases there is complete recovery (temporary spinal paralysis). But in the great majority of cases a greater or less degree of paralysis remains permanently. Of the paralyzed extremities some may entirely recover, while in others, especially the lower, groups of muscles remain permanently paralyzed. The improvement is most rapid during the first six or eight weeks, and then continues very slowly for six or eight months, and, with proper treatment, possibly without it in some instances, the muscles may gain in strength for a year or two.

The profoundly paralyzed muscles soon undergo atrophy. This is usually observed within a week or two. When their power is restored the muscles regain their volume, but in those permanently paralyzed the atrophy may be so complete that no muscular tissue can be felt beneath the skin. The atrophy is sometimes concealed by the accumulation of adipose tissue.

Along with the muscular atrophy are observed changes in the electrical reactions. These are very important, both as diagnostic and prognostic indications. When the paralysis is profound, the faradic irritability of the nerves and muscles is diminished in from three to five days, and entirely abolished in a week. When, on the other hand, at the end of the second week the faradic contractility of the muscles, though diminished, is not abolished, the muscles will not remain paralyzed permanently. The changes in the galvanic reactions are those characteristic of the reaction of degeneration—first, increased galvanic irritability, then anodal closure contraction stronger than cathodal closure—the reverse of the normal formula; finally, the galvanic reactions become weaker and may be abolished. In muscles not so profoundly paralyzed there is usually only a quantitative change in the electrical reactions, a diminution of the faradic and galvanic irritability, but no qualitative change, no reversal of the normal formula of contractions.

The bones and joints are often greatly altered. The bones may be arrested in their development, be much shorter and narrower than the corresponding ones on the other side, and also be more yielding or friable. In this way the whole limb remains smaller than its fellow. This is especially true of the lower extremity, which may be from two to six inches shorter than the sound one; but the arm is also frequently reduced in size, and even the bones of the pelvis are sometimes arrested in their development. The changes in the bone need not correspond to those in the muscles. There may be considerable atrophy of muscles and but little change in the bones, or *vice versa*.

The joints may become deformed and abnormally movable, due partly to atrophy of the cartilages and the epiphyses of the bones, partly to a weakness of the ligaments of the joints. The skin is usually cold and cyanotic, and sometimes becomes dry, liable to indolent sores, etc.

The most characteristic features of the long-standing disease are the various deformities which occur. Various factors play a part in their production. One is the weight of the limb, as when the child lies on its back the paralyzed foot naturally falls into a state of extension, and talipes equinus results. A more important factor is the state of the muscles. The deformity is greater when not all of the muscles of a joint are paralyzed. The limb is then drawn and maintained in its new position by the unantagonized sound muscles, which may subsequently become shortened to adapt themselves to their changed relations. Some other factors may come into play, as retraction of the connective tissue related to the atrophied muscles. In fact, the explanation of the production of deformities is still largely a controversial point.

The most common deformities are the different kinds of club-foot, especially equino-varus. Among others are various contractures of the knees and hips, lateral and antero-posterior curvature of the spine, and contractures of the hands, wrists, and arms.

Apart from those mentioned there are, as a rule, no nervous symptoms. In the very beginning there may be some pain and hyperæsthesia, and weakness of the blad-

der. But these soon disappear, and then there are no sensory symptoms, and the functions of the bladder and rectum are normal. The mind is clear, the general health unaffected, and the patient may live to old age.

(b) *Acute Anterior Poliomyelitis of Adults.*—The disease is ushered in by fever and nervous symptoms, as in children, though convulsions have not been observed. The paralysis sets in rapidly, the paralyzed muscles are flaccid, the permanently paralyzed muscles undergo rapid atrophy, and there are changes in the electrical reactions, just as we found them in children. Less frequently than in children is a single limb affected. Often the four extremities, at least the lower, are paralyzed, though the upper may be alone affected. Improvement soon begins, and, as in children, rare cases of recovery occur. As a rule, more or less paralysis remains permanently. The deformities, which appear at a later period, are not so great as in children, for the bones have attained their full size, and the joints are firmer.

Morbid Anatomy.—The great majority of post-mortem examinations have been made in cases where the disease had existed many years. In these extensive changes have been found in both the white and gray matter of the cord, as well as in the nerves and muscles. But most of these are to be considered secondary changes. In the few cases where an examination could be made at a comparatively early period (after the disease had existed four weeks or longer), evidences of myelitis were found, affecting chiefly the anterior cornua, and, to the largest extent, the cervical and lumbar enlargements. The large ganglion cells were always affected, and their destruction appeared to correspond to the extent of permanent paralysis. It is now generally believed that the paralysis, as well as the trophic changes in the muscles, bones, etc., is due to the destruction of these cells—which have both motor and trophic functions—or to the severance of their relations with the peripheral nerves. The acuity of the inflammatory process accounts for the rapid onset of the paralysis, and the considerable resolution of the pathological process which takes place explains the improvement which is always observed.

The naked eye appearances in recent cases are sometimes negative; sometimes there is indistinctness of outline on section, and discoloration and diminution of size of the anterior cornua. In several instances distinct foci of red softening were found. The seat and extent of the pathological changes are more accurately seen in the microscopical appearances. Foci of disease may be found in various parts of the cord, especially the anterior gray matter, while those of greatest intensity are usually in the cervical or lumbar regions. They may reach for some distance up and down the cord, occupying, at the same time, but a part of the anterior cornua. These are, usually, foci of red softening, in which the blood-vessels are much dilated, and granular cells appear in more or less abundance, and where the nervous elements, large ganglion cells and nerve-fibres, have mostly disappeared. The areas of disease may be distinctly circumscribed, and the neighboring tissues be entirely normal, or a slight and more diffuse inflammation may be observed to extend beyond this in various directions.

Occasionally there is found slight sclerosis of the antero-lateral columns, and diminution of their size, while the anterior roots, those corresponding to the diseased areas, are usually more or less atrophied.

In old cases, where the disease has been extensive, changes are readily seen by the naked eye. The anterior cornua, and often the antero-lateral columns, are much shrunken, and the anterior roots greatly atrophied. On microscopical examination quite circumscribed lesions are usually found in the anterior cornua of the cervical or lumbar enlargements, which are composed mainly of fine wavy connective tissue, with corpora amylacea and pigment granules, and in which the nervous elements have mostly disappeared. If ganglion cells are present they are usually in various stages of degeneration. At the same time the ganglion cells are often reduced in number in other parts of the cord, which may present other slight pathological changes.

In the antero-lateral columns, either in the immediate neighborhood of the greatest changes in the anterior cornua or involving a greater part of those tracts, are evidences of sclerosis, increase of the neuroglia, and atrophy of nerve-fibres.

The muscles present pathological changes corresponding to the intensity of the disease. Sometimes a few normal muscular fibres are found among others which are to a greater or less degree degenerated. In other instances the muscular fibre has altogether disappeared and been replaced by connective or adipose tissue.

More or less degeneration and atrophy are also found in the peripheral nerves, tendons, bones, and joints.

Diagnosis.—Usually a diagnosis is easily made, on account of the striking and characteristic features of the disease. These are flaccidity of the paralyzed muscles, altered electrical reactions, rapidly developing atrophy, and loss of the reflexes, together with absence of sensory or other nervous symptoms.

In young children pseudo-paralysis from disease of bone or other surgical affection might be mistaken for infantile paralysis, but a careful examination, or the lapse of a short period of time, would clear up the diagnosis.

Cerebral infantile paralysis can be distinguished by the absence of pathological atrophy, the normal electrical reactions, presence of the reflexes, the frequent involvement of the intellect, and the hemiplegic form of the paralysis.

The differentiation of hæmatomyelitis, or hæmorrhage into the substance of the cord, will often be impossible. The same is true of some cases of neuritis, though tenderness over the nerve and presence of anæsthesia or other sensory symptoms will usually point to the true disease.

In transverse myelitis there are usually indications of disease of the posterior as well as the anterior part of the cord.

Compression myelitis from Pott's disease presents, usually, the appearance of spastic paralysis, exaggerated tendon reflexes, etc.

Prognosis.—It is possible that some of the fatal cases of convulsions in children were in the initial stage of this disease; otherwise it is not attended by serious danger to life. The prospect is less favorable as regards the paralysis, more or less remaining permanently in most cases. The electrical current is of great value in informing us at an early period as to the probability of permanent paralysis. The information to be gained from it has already been mentioned. The greatest amount of improvement will take place in the first two months. It may be much furthered by proper treatment, and may even continue after a year or more has elapsed.

Treatment.—The early symptoms—fever, etc.—require chiefly rest in bed. Ergot and belladonna have been recommended, on the theory that they limit the inflammation through their influence on the circulation. Applications of ice to the spine, and revulsive applications, have been made for the same purpose. The administration of iodide of potash to promote the absorption of inflammatory products seems appropriate treatment. Electrical applications are often made at an early period. The object of making them, at this time, is to directly influence the spinal cord. For this purpose a large electrode should be selected and applied over the spine, while the other is applied to a distant part, for in this manner the largest quantity of the current may be expected to reach the cord. The positive pole is usually applied to the spine, and as near as possible to the seat of the disease—for instance, to the cervical spine if the upper, to the lower dorsal and lumbar spine if the lower, extremity is paralyzed.

At a later period the current should be applied to the paralyzed nerves and muscles. It must now be looked upon as one of the most valuable agents in treatment. The faradic current is appropriate if it can produce muscular contractions; otherwise the galvanic current should be selected. Duchenne, who was an enthusiast on the subject, believed he could create entire muscles out of a few fibres by means of faradization. At the same time

massage of the muscles, and other gymnastic exercises, should be instituted.

Arsenic and strychnine have been extolled for their power over the paralyzed muscles. Cod-liver oil, tonics, open air, and all else that can invigorate the system are indicated.

During this time efforts must also be made to counteract the tendency to deformity. In this effort the measures already mentioned—electricity, gymnastic exercise, especially the frequent stretching of the retracted muscles—accomplish much. Avoiding positions in which the weight of the limb may cause deformity, sometimes easy walking, holding the joints in proper positions, but not too firmly fixed, may all assist in preventing deformities When the latter are well marked, suitable apparatus, sometimes tenotomy, etc., are called for.

Philip Zenner.

SPINAL CORD DISEASES: ACUTE ASCENDING PARALYSIS.

Synonym; Landry's Paralysis.

DEFINITION.—A rapidly progressing paralysis, usually beginning at the lower extremities, extending to the upper extremities, the muscles of the trunk, and finally to those supplied by the cranial nerves, death often resulting from paralysis of respiration. The paralyzed muscles are flaccid, but there is no special atrophy, and no alteration in the electrical reactions. There are slight, if any, symptoms on the part of sensibility, bladder, or rectum, no bed-sores, and usually little fever. There are no anatomical changes to account for the symptoms.

In 1859 Landry gave an accurate description of this disease, noting, at the same time, the absence of appreciable anatomical changes, and since that time many similar cases have been reported. In 1875 Westphal, in connection with a report of four cases, gave a critical review of the subject. He excluded a number of reported cases in which some anatomical changes were found post mortem, and made an absence of the latter an essential feature of the disease. His views have been very largely accepted.

The absence of anatomical changes in the nervous system has been pronounced by most competent pathologists, such as Vulpian, Cornil and Ranvier, Bernhardt, Westphal, and Kahler and Pick, so that the accuracy of their observations cannot be questioned. But, especially since Westphal's report, a number of cases have been recorded, whose histories are almost or altogether in full accord with those of acute ascending paralysis, in which lesions in the nervous system were found. We must leave it to the future to decide whether the latter do not belong to the same class of diseases, or whether the negative results in earlier cases merely indicate that the pathological changes had not yet progressed far enough, or were not sufficiently intense to be recognized by our present methods of examination.

ETIOLOGY.—The disease occurs chiefly in men, and in adult life. It does not seem to occur specially in those predisposed to nervous diseases. Exposure to cold, suppressed menses, etc., have been assigned as causes. It sometimes occurs in syphilitic subjects, and some have believed, especially on account of the apparent results of treatment, that the disease is sometimes of syphilitic origin, but post-mortem examinations find nothing to uphold this view. It has occurred in the course of, or during convalescence from, acute diseases, as typhoid fever and diphtheria. Westphal believes that some toxic agent causes the disease. In a case of Baumgarten's, where the disease complicated splenic fever, bacilli anthracis were found in the blood and in the cord.

SYMPTOMS.—The disease is sometimes ushered in by shooting pains in the back and legs, sometimes by slight fever, or there may be a general sense of debility and discomfort for some days preceding the paralysis. Numbness and tingling in fingers and toes are not infrequently felt, and this is often the only sensory symptom. The paralysis begins generally in the lower extremities. From a degree of weakness which the patient first complains of, it increases rapidly to complete paralysis. Either at the same time, or shortly afterward, the arms become affected, the paralysis rapidly increasing in intensity. Then the muscles of the abdomen are affected, making defecation, etc., difficult; next, the muscles of the chest, causing respiratory difficulties. Lastly, the cranial nerves are involved, chiefly the hypoglossal and pneumogastric, causing difficult deglutition, indistinct speech, and difficult breathing, the latter often in paroxysms, but occasionally the seventh and other motor cranial nerves are also paralyzed.

The paralysis does not always follow this course. It occasionally begins in the upper extremities, occasionally in the cranial nerves. In the latter case there is usually a very rapidly fatal issue.

The further characteristics of this disease are negative symptoms. The muscles are quite flaccid, but they do not undergo atrophy, at least to any considerable extent, and the electrical reactions remain normal. In a number of instances the patellar tendon reflex was abolished. There are no bed-sores, and no, or at least very slight, disturbance of the bladder and rectum. Sensory symptoms are slight, or altogether absent. Anæsthesia of the soles of the feet, or other parts, has been observed. Usually the general health is but little disturbed, and the mind is unaffected.

The duration of the disease is from a very few days to several weeks, the average being from ten to twelve days. A fatal issue is usually brought on by paralysis of respiration.

But the disease does not always terminate fatally. Of ten cases mentioned by Landry, eight recovered. But there is often room for doubt whether cases that recover really belong to this disease. In favorable cases the disease is usually arrested before it reaches the cranial nerves, though cases of recovery are reported even after the latter have been affected. The progress toward improvement is usually in an inverse order to that of attack, the part affected last being the first to improve. The patient usually remains weak for a long time after the more pronounced paralysis has disappeared. The progress of convalescence is liable to interruptions from relapses, which may even take a serious course.

MORBID ANATOMY.—It has already been stated that, so far as the central nervous system is concerned, the results, in cases generally accepted as those of this disease, were negative. Enlarged spleen, lymphatic glands, etc., as in cases of infectious diseases, were found in a number of instances. This gives some basis to Westphal's view, that the disease is due to a kind of intoxication.

Eisenlohr reported a case (Virchow's Archiv, lxiii., page 73), with almost typical history, of acute ascending paralysis, in which there were slight evidences of myelitis and small capillary hæmorrhages in the medulla oblongata. In a case of Kümmell (Zeitsch. f. klin. Med., ii., page 272), coming on during the convalescence from typhoid, and with a typical history of ascending paralysis, small hæmorrhages in the medulla oblongata were found. Schulz and Schultze reported a case (Archiv f. Psychiatrie, xii., page 457) with the usual symptoms of ascending paralysis, only that the course was a slow one, its whole duration being nearly two months, in which the electrical responses of most of the paralyzed muscles were those of the reaction of degeneration. But the electrical test was not made until about the sixth week of the disease, and, as pointed out by the authors, it is not improbable, if tested in the first or second week, as in other cases, the electrical reactions might have been normal. The post-mortem revealed a fresh myelitis, chiefly of the motor tracts of the cord, of the anterior gray matter, and of part of the medulla oblongata. Lastly, Hoffman (Archiv f. Psychiatrie, xv., page 140) reported a typical case of ascending paralysis, only that there was double facial paralysis, with some diminution of the electrical irritability of the right facial nerve and muscles, though the electrical reactions were elsewhere quite normal. On post-mortem examination a moderately intense meningitis, and slight myelitis, chiefly of the antero-lateral columns in the cervical and dorsal regions, were found. In none of these cases did the extent of morbid

changes appear to correspond to the intensity of the symptoms manifested during life, but they, nevertheless, indicate that those symptoms were dependent on a palpable lesion.

Diagnosis.—The rapidly progressive course, the presence of mostly motor symptoms and normal electrical reactions, will usually distinguish these cases.

Acute multiple neuritis can usually be distinguished by the sensory symptoms, pain, tenderness, anæsthesia, etc., and by the atrophy of muscles and altered electrical reactions. Some cases of subacute anterior poliomyelitis run a very rapid course, so that they closely simulate this disease. But there is greater likelihood of muscular atrophy and altered electrical reactions, bulbar symptoms usually appear at a much later period, and the disease runs a less rapid course.

Acute central myelitis, also, often causes an ascending paralysis, and runs a rapid course. But in this disease the sensory symptoms, anæsthesia, etc., are prominent; there are paralyses of the bladder and rectum, acute decubitus, fever, etc.

Prognosis.—The disease must always be looked upon as a serious one. It is true, cases, apparently of this affection, recover, but in most of these the disease is arrested at an early period. The more rapid the progress of the disease, and the earlier bulbar symptoms appear, the more unfavorable the prognosis.

Treatment.—Cold to the spine, cupping, and blisters have been tried at an early period. Iodide of potash should be administered, especially where there is a syphilitic history. In the latter case inunctions of mercury should also be tried. In Schulz's case hot baths seemed to do much harm, while the constant current to the spine was followed by considerable improvement.

In cases running a favorable course, the use of electricity, hydrotherapy, tonics, change of air, etc., are indicated.

Philip Zenner.

SPINAL CORD DISEASES: ACUTE SPINAL MENINGITIS. *Synonyms:* Acute inflammation of the spinal pia mater and arachnoid; lepto-meningitis spinalis acuta; perimyelitis and arachnitis.

This disease, which is the most frequent and important of the affections of the spinal meninges, is an acute inflammation of the spinal pia mater, with implication to a greater or less extent of the arachnoid, the sub-pia connective tissue, the connective tissue between the pia mater and arachnoid, and the internal surface of the dura mater. As a sporadic affection it is rare, but it is often found associated with lepto-meningitis of the brain, constituting the affection known as epidemic cerebro-spinal fever.

Pathological Anatomy.—This affection may be divided pathologically into three stages: First, the stage of hyperæmia, or commencing exudation; second, the stage of purulent or fibrinous exudation; and third, the stage in which chronic changes are established.

In the first stage, which is seldom observed post mortem, the pia mater appears thickened, opaque, rosy, or dark red in color, and dotted with hæmorrhagic extravasations; the tissues around are swollen from infiltration of serum; the spinal fluid is increased in quantity, and turbid. The sub-pia connective tissue, the arachnoid, the connective tissue between the pia mater and arachnoid, and the internal surface of the dura mater are also congested, the hyperæmia frequently extending to the cord and nerve-roots arising from the affected region.

In the second stage the spinal fluid becomes more and more turbid, and assumes a sero-purulent appearance, containing numerous flakes of fibrin. The pia mater, and the connective tissue underneath the pia, and between that membrane and the arachnoid, become more and more opaque and softened, and are converted into a gelatinous mass by a more or less infiltrated, dense, whitish, fibrinous, or purulent exudation, composed of leucocytes and fibrin. This exudation is more or less resisting, and may appear in lamellæ. Small miliary nodules are found, in some cases, distributed along the course of the vessels of the pia mater, constituting tubercular spinal meningitis. The arachnoid is opaque, and sometimes adherent to the dura mater. The dura mater is hyperæmic, reddened, and opaque, and fibrinous flakes and plates are found adherent to its internal surface. Peripachymeningitic hæmorrhages occasionally occur. The nerve-roots are always involved; they are enveloped in thick masses of exudation, and are swollen and softened. The cord itself is pale, œdematous, or congested, and finally softened in spots or diffusely. Microscopical examination shows in the soft membranes of the cord all the signs of an exudative inflammation—abundant cell-infiltration, especially along the vessels; fulness of the capillaries; swelling and spreading of the bundles of connective tissue, and infiltration of cells in the nerve-roots. The nerve-fibres are swollen, granular, and beginning to break down; the axis-cylinders are swollen and granular, and the bundles of root-fibres entering the cord are similarly affected. In the cord the neuroglia is infiltrated with small cells and nuclei, or actual parenchymatous myelitis is found; the axis-cylinders are enormously swollen and breaking down; the medullary sheaths are cloudy and undergoing granular decay; in the gray substance swelling and œdema of the ganglion-cells occur; the central canal is closely packed with round exudation-cells.

The distribution of the exudation in the membranes varies greatly, both as regards its consistency and thickness and the longitudinal extent it occupies. As a rule, it is circular, covering the whole periphery of the cord, being thicker, however, at the posterior surface of that organ, and it extends the whole length of the spinal canal. The greater thickness of the exudate on the posterior surface has been attributed by some to the fact that the patients lie more on the back. This explanation would not hold good in one of my cases, here reported, where the same thing was observed in a patient who almost constantly lay on his side or face. Others have thought this difference in the thickness to be due to the richer supply of nerves in the posterior region. When the meningitis is limited in longitudinal extent to the length of one or two vertebræ, the inflammation is, as a rule, due to disease of the bone. It is very seldom that the exudation extends upward from the spinal canal to the membranes of the brain, though this has occasionally been seen, as in one of Ollivier's cases and in the second case reported by me.

The third stage, or that in which chronic changes are established, is, of course, only seen in those cases in which acute inflammation gives place to a chronic one. The most common of these changes are opacity and thickening of the spinal membranes, with the formation of adhesions; accumulation of fluid in the arachnoid space (hydrorrhachis); and sclerosis or atrophy, either diffused through the cord or affecting isolated portions or systems. When absorption has taken place, there is, of course, no third stage.

Etiology.—The causes of acute spinal meningitis are still very obscure. It occurs more frequently in the young and aged than in those in middle life, but is not altogether limited to these extremes, a number of cases having been observed in adults. Men seem to be more often affected by the disease than women; but this depends, probably, rather on the fact that they are more exposed to traumatism by the nature of their occupations, and that they are more given to excesses and dissipation, than it does upon any special susceptibility inherent in the sex.

Of the known predisposing causes, the most important are a scrofulous or tuberculous constitution; insufficient food; damp dwellings; sexual, alcoholic, and other excesses, and syphilis.

Omitting the epidemic and infectious influences which affect the occurrence of cerebro-spinal meningitis, with which we are not here concerned, and not considering those cases of extension of the affection from the cerebral meninges to the spinal membranes, as in the tubercular and other forms, the following are credited with having been the exciting causes of this affection in some instances: Injuries to the spinal column from blows, falls,

or railroad accidents, causing either fracture, dislocation, or concussion of the spine; gunshot wounds of the spine, or punctured wounds of the membranes, as in the operation for spina bifida; violent bodily efforts, as in lifting a heavy weight; sacral eschars perforating the dura mater; a sudden fall into cold water; a cold-air current striking the back when the person is sweating; exposure to wet and cold, as from sleeping on damp ground, or standing long in water while working; the suppression of the menstrual and hæmorrhoidal fluxes; suppressed perspiration of the feet; communication of a peripheric neuritis to the spinal meninges, observed in a case of tetanus; dentition; the puerperal state; the opening of an abscess from neighboring parts into the spinal canal; and the extension of inflammation from parts around into the vertebral canal. The following constitutional diseases are known to have been occasionally complicated with acute spinal meningitis: Acute rheumatism; pneumonia; scarlet fever, and the other exanthemata; and pyæmia.

Of these causes the following are rather doubtful: Dentition; the disappearance of acute exanthemata; the suppression of the menstrual and hæmorrhoidal fluxes; suppressed perspiration of the feet.

Symptoms and Clinical History.—In the study of the clinical history of this disease it will be best to divide it into two stages: First, that of congestion and beginning exudation, the irritative stage; and second, that of complete exudation, or compression.

First Stage.—Acute spinal meningitis is only in exceptional cases preceded by the usual symptoms denoting inflammatory action, such as chilly sensations, restlessness, headache, etc. Its onset is generally sudden, a sharp rigor being the first indication of the disease in most cases. This is followed by an irregular fever, and a quick, hard, full pulse. Pain in the back, either confined to a limited region or extending along the whole spine, makes its appearance. This pain, at first dull, soon becomes acute, boring or shooting in character, and is greatly increased by movements of the trunk and limbs; but, as a rule, it is not affected by pressure on the spinal processes of the vertebræ. The pain soon extends around the body, in the form of a girdle, and down the limbs; the alternate passage of a hot and cold sponge along the spine increases it; it is greatest at the site of the principal lesions. In a very short time contraction of the back and limbs is observed, and when the cervical region is involved the head is drawn backward and arched in a condition of more or less complete opisthotonos. Hyperæsthesia and various paræsthesiæ of the skin are well marked. The muscles of the trunk and extremities are also hypersensitive, and the patient remains motionless in bed, with the limbs rigid, not from paralysis, but from fear of the acute pain which accompanies the slightest motion; the muscles are in a state of tension or spasm, which is increased by motion, but not by reflex irritation; there are also spontaneous muscular twitchings, giving rise to severe pain. Dyspnœa, amounting in some cases to asphyxia, is sometimes seen, owing to implication of the respiratory muscles. The pupils are irregular; sometimes they are normal, at other times they may be contracted or dilated, or one of them only may depart from the normal. Violent headaches, vertigo, vomiting, irritation or paralysis of the oculo-motor nerves, together with delirium and coma, are due to invasion of the cerebral meninges. The reflexes, skin and tendinous, are, as a rule, exaggerated in this stage, and there is also exaggerated electrical reaction. Functional derangements of the bladder and rectum appear early in the disease; there is at first costiveness, with retention of urine from spasms of the sphincters of the anus and bladder, then afterward dribbling of urine from overdistention, and later on paralysis of the sphincters. The urine is at first dark, scanty, and cloudy from the urates, but later on it becomes abundant, light, and clear; in some cases an excess has been observed, due probably to direct nervous stimulation of the secretory centres in the cord; in rare cases mellituria has occurred. The abdomen is sunken and tense, and free from meteorisms and swelling; diarrhœa is rare. Eruptions on the skin have occasionally been observed, but not so frequently as in the epidemic form of the disease.

The duration of this stage is variable, lasting from two or three days to a week or more, the disease being occasionally, though very rarely, arrested at this period. At times deceitful signs of temporary improvement will show themselves, but are soon followed by symptoms denoting invasion of the cord or of the meninges of the brain. Death occasionally closes the scene at this period; but this is rare, unless the affection is a sequel to some exhausting disease, or unless the membranes of the brain and medulla are severely affected. As a rule, the symptoms of irritation belonging to the first stage gradually give way to symptoms of paralysis of motion and sensation, denoting compression of the cord and nerve-roots.

Second Stage.—The pains in the back and limbs still persist, but have lost their acuteness; the patient feels dull and heavy; cutaneous and muscular hyperæsthesia are replaced by anæsthesia and muscular paralysis, with contracture and atrophy; the reflexes and electrical reaction become diminished, and sometimes altogether lost; the sphincters of the anus and bladder become paralyzed, and there is incontinence of urine and fæces; more or less paresis, or paralysis, of the extremities exists, the extensor muscles being generally more affected than the flexors; bed-sores and cystitis supervene as dangerous complications. Paralysis of the muscles of deglutition and of the tongue, usually a fatal complication, denotes invasion of the medulla oblongata. Rapidity and irregularity of the pulse and respiration, occasionally observed at this stage, are due to compression of the vagus. The temperature at times rises to 106° or 108° F., denoting extension of the disease to the cerebral meninges; delirium and coma ensue, and speedily lead to a fatal termination, but more often death is brought on by exhaustion and marasmus.

The location of the disease at different levels of the cord naturally causes variations in the symptomatology; as we have said before, it is more common to see the meningitis extending along the whole spinal canal, but at times, in traumatic cases especially, it is more localized.

When the lumbar and sacral regions are alone affected, the pain is felt in the sacrum and loins; the stiffness is limited to the lower part of the spine; the pain radiates to the hypogastrium, perineum, and lower extremities, and the spasms and paralysis are limited to those parts; the urinary troubles are very severe.

When the dorsal region is also involved, the pain and stiffness extend higher up in the back, as far up as the shoulders; there are disturbances of respiration, etc., added to the symptoms manifest in the lower extremities.

When the cervical region is also implicated, there are, in addition, stiffness and pain in the back and neck; excentric pain, extending to the upper extremities; difficulty in breathing and swallowing; derangement of the heart's action, pupillary symptoms, etc.

When the inflammation extends to the medulla oblongata and base of the brain, in addition to the spinal symptoms those of a cerebral nature are observed, such as violent headache, vomiting, vertigo, delirium, trismus, oculo-motor paralysis, disturbances of speech and respiration, and coma.

Some of the symptoms above enumerated are due to the inflammation of the meninges, but the physiological explanation of by far the greater number of these is to be found in the implication of the nerve-roots or periphery of the cord itself, almost invariable accompaniments of spinal meningitis. For instance, the pain in the back, according to Hallopeau, is not due to irritation of the posterior nerve-roots, but is caused by irritation of the meningeal nerves; the spinal meninges have been demonstrated, he says, not to be sensitive in their normal condition, but become extremely so when in a state of inflammation, and he bases his argument on the fact that the pain is almost always absent in myelitis. That irritation of the nerves of the pia and dura mater is account-

able for a certain amount of this pain admits of no doubt, but the very character of the pains—their excentric nature, occurring in portions of the body which derive their nerve-supply from the affected regions of the cord—prove beyond contradiction that irritation of the posterior nerve-roots acts as an important factor in their production. The same explanation must be given for the hyperæsthesia and paræsthesia found in different portions of the body.

The stiffness of the back and extremities, the muscular tension, the contractures and spasms, are due chiefly to direct irritation of the motor apparatus—that is, in part to inflammatory irritation of the anterior roots, in part to irritation of the motor paths in the lateral columns of the cord by secondary points of myelitis. That these motor disturbances are in some cases caused in a reflex manner, by the abnormal irritation of the posterior roots, must be also admitted, as well as the fact that this muscular tension is half voluntary in character, or is increased by a voluntary act which has for its object the prevention of movement when all movements are so painful.

The motor and sensory paralyses, neuralgia, and anæsthesia of the extremities which occur in the later stages of this disease are due to affection of the anterior and posterior nerve-roots, but it is not impossible that myelitic points in the white columns of the cord contribute, in some cases, to the production of this paralysis.

The retention of urine occurring early in the disease is explained by the direct or reflex spasms of the sphincter of the bladder. The later paralysis of this viscus is due to the same causes that produce the paraplegia.

The disturbances of the digestive apparatus and the costiveness which accompany this affection are referred by Koehler to spasm of the intestinal muscles and consequent interference with peristaltic action, and to the spasmodic tension of the abdominal muscles. But to this must be added the sluggishness and weakness which are so characteristic of intestinal movements in spinal diseases.

The disturbances of respiration which occur, from simple accelerated and difficult breathing up to extreme dyspnœa and asphyxia, are due to implication of the cervical roots, causing tension and spasms or paralysis of the respiratory muscles, or to implication of the white matter of the cervical cord, in which are situated the respiratory paths, or to an extension of the disease to the respiratory centre in the medulla oblongata.

The pupillary changes may be due either to irritation of special fibres in the cervical cord or to disturbances of the oculo-motor nerves by extension of the disease to the brain.

The symptoms denoting invasion of the brain have been referred to.

Course, Duration, and Termination.—In the most acute forms of the disease death may occur in a few hours, but more generally it occurs in three or four days, from asphyxia. In less violent cases the duration of the disease is two or three weeks, recovery ensuing at the end of that time in exceptional cases. In other cases the violence of the symptoms is abated, but the patient remains an invalid for a number of weeks or months, improvement in the paralyzed muscles being very slow; and at times contractures and paralysis of certain groups of muscles remain permanent. In other cases, again, the acute symptoms subside and the disease assumes a chronic form, which is usually associated with myelitis, the patient dying, later on, of cystitis and bed-sores.

The following two cases give a clear clinical illustration of spinal meningitis; hence their insertion here.

Case of Acute Meningitis ending in Recovery.—John G——, aged thirty-five, born in England; a machinist by occupation; has been a hard whiskey-drinker for years; smokes and chews to excess; has never contracted syphilis; gives no history of hereditary predisposition. About June 16, 1883, he went on a spree, and slept all night on the ground in one of our public squares, where he was picked up by the police next morning. The day previous had been a very rainy one, and the ground, on which he must have lain for hours, was quite wet. When aroused he felt stiff in the legs, but was able to accompany the officers to the jail, and on that same day he was discharged by the police-court and was admitted into Charity Hospital, in the ward for nervous diseases, complaining of great pain of a shooting character in the lumbar and dorsal regions of the spine. The pain extended all around his body at the level of the nipples, and shot down the legs; these felt numb and stiff, but he was still able to stand; his pulse was hard, full, and fast, about 104 per minute; his respiration somewhat accelerated, and his temperature 101½° F. I saw him on the next day, and made the following notes of his case: Patient is well nourished; general appearance good; complains of sharp, shooting pains along the spine, from the neck down, extending around the body and around the arms and down the legs; this pain is not increased by pressure on the spinous processes, but the slightest movement of the body or extremities brings on an exacerbation; the back is stiff and arched, and the legs flexed on the thighs, and the thighs on the pelvis; he is unable to extend the extremities, not that any paralysis exists, but from the fact that the attempts at motion give rise to severe paroxysms of pain; the muscles in the trunk and extremities are tense and contracted, and the patient complains at times of involuntary twitching, giving rise to exquisite pain; his bowels are constipated, and he has passed no urine since admission. With a soft catheter over a pint of highly colored urine was drawn from his bladder. The pulse is 112, full and hard, and the temperature has reached 102° F. The patient's mind is clear, and, aside from some frontal headache, he complains of no disorder about the head. A brisk purgative of calomel and bicarbonate of soda, each fifteen grains, was prescribed, and cold applications were made to the back, the patient being ordered to lie on the side, which position he had, however, already assumed of his own accord. Quinine sulphate, in five-grain doses, was also given every four hours, and a tablespoonful of the following mixture after each dose of quinine: Fluid extract of ergot, ʒ iv.; potassium bromide, ʒ iv.; syrup of orange-peel and water, each ℥ iij.

On the 18th the patient was found very restless; the pains still continued to be intense in the back and lower extremities, which were found still more stiff, the hands and arms felt numb, and he complained of shooting pains also in these. The bowels had acted several times, but his urine had to be drawn, the slightest effort to pass water being accompanied by excruciating pain; the patient's position was that of opisthotonos. The temperature was 102° F., pulse 110. The mind was clear; there was no vomiting; respiration hurried, but otherwise normal. The same medication was continued, with five drops of Batley's sedative added to each dose of bromide of potassium.

During the next week the patient rested somewhat better, but there was no improvement in his symptoms; the urine was still retained; the disease, however, seemed to have made no noticeable progress. A considerable quantity of milk and several eggs were taken, and retained, every day; the temperature oscillated between 101° and 103° F., with no uniform remission. On the seventh day the quinine and Batley's sedative were stopped, the bromide and ergot continued; a saline purgative—Glauber's and Epsom salts, each ℥ ss.—was given, and the cold applications to the back were replaced by applications of tincture of iodine along the spine.

The patient's condition was now as follows: Pain somewhat diminished, but back and extremities feel stiff, numb, and heavy; sensation to touch and pain, tested in hands and feet, is blunted and retarded; patient finds considerable difficulty in moving his legs and arms, but when these are moved the pain in the back is not so greatly increased as on the previous days. The urine is still retained, and dribbles from him unawares; his bowels have not acted since the second day. On July 8th, the twentieth day of the disease, the temperature has for the first time fallen to normal; the pulse is weaker and faster, 120 to the minute; the urine still dribbles, and has to be withdrawn; the bowels have acted several times since last account; the pain and stiffness in the back are still present, but bearable as long as the patient remains at

Spinal Cord.

rest; the paresis and anæsthesia of the lower extremities are almost complete, and the patient complains of burning and creeping sensations in these parts; there is a slight wasting of the muscles; the skin over the sacrum is reddened, and a bed-sore is feared. The upper extremities are numb and weak, but the patient is able to move them slowly. Counter-irritation, by means of tincture-of-iodine applications to the spine, is still kept up, and all medicine, except the following, discontinued: Potassium iodide, gr. v.; potassium bromide, gr. x.; four times a day.

On August 12th the patient is able to sit up in a chair; the dribbling of urine has stopped, and the bladder is slowly evacuated by natural means; the bowels, though sluggish, act without assistance; the back and lower extremities are as yet stiff and a little painful, but the patient has obtained some control over the latter and is able to move them slowly; the wasting has not progressed; sensation is evidently better than at last report; the upper extremities have improved; there is a superficial sore over the sacrum, which, however, shows healthy granulations. The potassium iodide, in ten-grain doses, three times a day, is still continued; daily mild galvanic currents, alternately ascending and descending, are applied to the spine, and the muscles of the lower extremities are faradized; the faradic irritability is somewhat diminished.

At the end of September the patient was able to go about unassisted, and was discharged, cured, on October 10th, nearly four months after admission, nothing but a slight stiffness of the back and lower limbs remaining.

Case of Acute Spinal Meningitis, with Cerebral Complications, ending fatally on the Ninth Day. Autopsy.—A. P——, white, male, aged twenty-three, was admitted in the ward for nervous diseases in Charity Hospital, under my care, complaining of acute pain in the spine, extending from the head to the sacrum. The back was considerably stiffened, and the lower extremities were drawn up; the pain also extended to the trunk and all four extremities, and, though continuous, would be considerably increased at times; pressure over the vertebræ seemed to give rise to no exacerbation of the pain, but the slightest motion of the spine, either backward or forward, would cause the patient to scream with agony; there was considerable hyperæsthesia of the legs and arms, and pressure on the same gave rise to immediate complaint; the muscles of the extremities were contracted; the urine dribbled away, and the bladder was full; the bowels were costive; temperature 103° F.; pulse hard, full, and 116 a minute; respiration jerky, 24 to the minute. The patient said that he had been taken with uneasy feelings and weakness in his back and head three days ago; that this had so increased the following day that he was forced to keep his bed, when a chill, followed by fever, came on. He was occupying a bed on the fourth floor of a boarding-house, and on the third day, as the symptoms seemed to be aggravated, he requested to be taken to the hospital.

After admission a saline purgative was administered, cold applications to the back were immediately begun, and quinine was given to reduce the temperature, and sedatives, such as opium, bromide, and chloral, used to soothe the pain. On the two following days the patient's symptoms were found more severe; the pains in the back and limbs were excessive; the opisthotonos was complete; the urine was passed involuntarily, and the patient had had two unconscious motions from the bowels in bed; the temperature was 104½° F.; the pulse very rapid, soft, and irregular, 124 to the minute; and at times there was considerable delirium of a most violent kind. On the next day—the sixth of the disease—the patient's condition was found considerably aggravated; the delirium, though milder, was almost continuous; and other troubles, such as vomiting and eructations, were frequent; the respiration was rapid and labored, 32 to the minute, and deglutition was difficult; the pulse was scarcely perceptible; paralysis in the extremities had supervened, and the skin reflexes were almost entirely abolished. The patient's condition continued to grow worse, the delirium passing into coma, which ended in death on the ninth day of the disease, and the sixth day after his admission to the hospital.

Autopsy, held five hours after death, revealed a congested and œdematous condition of the lungs; heart full of fluid, dark-colored blood; other organs normal. Spinal marrow: Along the whole spine the internal surface of the dura mater was rosy; blood-vessels very much enlarged; opposite the lumbar enlargement, particularly, there was a slight fibrinous deposit on the internal surface of that membrane; the arachnoid was opaque, but showed no other evidence of disease; the spinal fluid was very abundant and sero-purulent; on the surface of the cord and in the meshes of the pia mater was a thick fibrinous deposit, which enveloped the whole cord and the nerve-roots; this deposit was thicker posteriorly, and diminished in density from below upward to the medulla, where it was very thin; the marrow was pale, and in some localities (at the lumbar and cervical enlargements) a little softened. At the base of the brain, and over the Sylvian fissure on both sides of the convexity, a thin exudate of fibrin was found; the cerebral fluid was increased, and the blood-vessels of the brain were much congested. The cord was preserved, by hardening, for microscopical examination, but, unhappily, the Pathological Department of the hospital was being rebuilt at the time and the specimen was lost.

This case, if we are to judge by the amount of post-mortem changes and the development of symptoms, was undoubtedly one of inflammation of the spinal meninges, progressing upward and implicating, secondarily, the cerebral meninges. As to its cause nothing could be ascertained, the patient being a laborer who had been out of work for some time; he was of temperate and regular habits, and had never had syphilis; he had received no blow and suffered no fall; he gave no history of hereditary predisposition to tuberculosis, and showed no evidence of this disease in any of the organs examined.

Diagnosis.—The diagnosis of acute spinal meningitis must be based on its sudden onset and the severity of its symptoms. The distinguishing signs, aside from fever and other general symptoms, are sudden, acute pain in the back, extending to the trunk and limbs, increased by motion, but not affected by pressure over the spine; rigidity of the back and extremities; hyperæsthesia and paræsthesia of the skin and muscles; retraction of the head; difficulty of breathing and swallowing; retention of urine and constipation; normal or exaggerated reflexes.

Dorsal muscular rheumatism is distinguished from spinal meningitis by the character of the pain, which is confined to the back, the absence of general and spinal symptoms, and its usually favorable termination.

Tetanus may be differentiated by the fact that the trismus appears first in that disease, by the absence of fever in the beginning, by the absence of hyperæsthesia, and by the fact that the exacerbations of pain and the spasms are brought about by peripheric irritation.

Myelitis can be recognized by the early and deep motor and sensory paralyses, and by the absence of stiffness in the back and neck, of the excentric pains in the limbs, and of hyperæsthesia of the muscles or skin, which characterize, especially, meningitis.

The diagnosis of tubercular meningitis must rest on general considerations, and on the association with basal cerebral meningitis.

Prognosis.—Acute spinal meningitis is always a grave affection; hence our opinion should always be guarded. When the symptoms are in general mild, the fever not very high, and when there is no extension to the upper portion of the cervical cord, in an otherwise strong and healthy individual, the outlook is more encouraging, but we should not be too hurried in prognosticating favorably.

Hyperacute and tubercular cases, or those caused by deep bed-sores, are nearly always fatal. Rheumatic and traumatic cases, when the lesions are moderate, are more favorable. Symptoms which show that there is early compression or implication of the cord itself, such as paresis or paralysis, twitching of the limbs, muscular

contractures, and anæsthesia of the skin, are generally unfavorable, as are also a high fever, progressive rise of temperature, extreme frequency and irregularity of the pulse, great difficulty of breathing, early signs of exhaustion, severe cerebral symptoms, and signs of implication of the medulla oblongata. The disease is also much more liable to terminate unfavorably in the very young and in the aged.

TREATMENT.—We know at present of no remedy that will act as a prophylactic in spinal meningitis; the avoidance of such of the causes as are known to have brought on the disease are, however, here to be recommended.

In the first stage of the affection our attempts should be directed to the reduction of the hyperæmia in the parts, and the moderation of the general symptoms; for this purpose the local abstraction of blood by cupping along the spine, the application of leeches to the neck, back, and perineum, cold applications to the back by means of ice-bags, the internal administration of large doses of fluid extract of ergot or ergotine and tincture of belladonna, are to be recommended, and have been found occasionally of benefit. The patient should be put in a quiet, airy room, and should rest on the side or face; antipyretics, such as quinine, salicylate of sodium, antipyrine, and antifebrine, should be used, if indicated, to lower the temperature; a brisk mercurial purgative, followed by salines, is also of use to cause derivation to the intestines. If the disease is of rheumatic origin, free, energetic diaphoresis will be of benefit. If the pains are very severe, sedatives, such as bromide of potassium, chloral hydrate, the preparations of opium and of hyoscyamus, or the moist pack, are indicated. To limit the amount of effusion, mercurial inunctions are considered of benefit. To relieve the retention of urine, the catheter should be regularly used.

When the disease has passed into the second stage all depressing medication must be stopped; the patient is to be well nourished, and tonics and stimulants are to be freely given. Absorbents, such as iodine, or the iodide of potassium, and ergot, in full doses; mercury, in small doses, internally and externally, in the form of an ointment; and counter-irritation along the spine, by means of tincture of iodine or otherwise, are to be used. Warm baths and moist packs are of marked utility. The use of sedatives is to be continued if required. The urine is to be attended to. The sequelæ, such as paræsthesia, anæsthesia, and the various motor disturbances, are to be treated by means of baths and the judicious use of the galvanic and faradic currents to the spine and affected parts. Care must be taken during convalescence to avoid all fatigue and bodily exertion.

SPINAL CORD DISEASES: CHRONIC SPINAL MENINGITIS. DEFINITION.—Chronic lepto-meningitis is an inflammation of the soft membranes of the spinal cord, unaccompanied by fever, slow and gradual in its evolution and course, which either develops spontaneously or follows acute inflammation of those parts. The symptoms, which are generally at first trifling, may gradually assume a more severe character as the inflammation extends from the membranes to the cord itself.

PATHOLOGICAL ANATOMY.—The lesions of chronic spinal meningitis are constant as regards their nature, though differing widely in intensity and extent in different cases, the changes being often only microscopic. On opening the spinal canal the spinal blood-vessels—the veins and capillaries mainly—are found congested, full of a dark-colored blood; the membranes, especially the arachnoid and pia mater, are hyperæmic, opaque, and more or less thickened and adherent; there are often adhesions between the pia mater and the cord, and between the former and the dura mater; the spinal fluid is abundant. The thickening of the soft membranes may be so great as to appear cartilaginous, and they may be pigmented in spots and present small points of extravasation of blood. Numerous small plates of calcareous matter are generally found upon the arachnoid, especially in the lumbar region. The dura mater is, as a rule, involved in the inflammatory process, and shows more or less marked congestion, opacity, and thickening. The extradural connective tissue also frequently participates in the process. Sometimes small granular growths of connective tissue may be found on the internal or external surface of the dura mater.

As a rule, the cord and nerve-roots are implicated to a varying degree and extent. Besides the degenerative changes occasionally induced by compression from the thickened membranes on that delicate organ, the processes which penetrate the spinal marrow from the pia mater are also thickened and swollen; at other times this inflammatory process spreads to the neuroglia of the cord, and we have then a true sclerosis in different regions and varying in extent, sometimes affecting the whole periphery of the cord and causing the usual secondary degenerative changes in the nervous elements in the posterior and antero-lateral columns; the changes occasionally extend to the gray substance and nerve-cells, whence results an atrophy of the cord.

The nerve-roots arising from the affected region are usually compressed, atrophied, and degenerated, and this atrophy and degeneration, as a rule, extend to the peripheral nerves and muscles. As sequelæ bed-sores and cystitis develop.

ETIOLOGY.—Chronic spinal meningitis very often follows the acute form, in which case its causes are the same as those of the latter.

As predisposing causes must be mentioned all debilitating influences; the abuse of alcoholics and tobacco; syphilis; chronic diseases of the heart, lungs, liver, and all conditions that give rise to impeded circulation in the vertebral and spinal veins; also sexual or other excesses.

Among the exciting causes must be mentioned frequent exposure to cold; the inhabiting of damp dwellings; constant exposure to bad weather; sleeping on damp ground; the abuse of alcoholics; the suppression of certain discharges of long standing, such as the menses, hæmorrhoids, sweating of the feet; and finally, traumatisms of moderate intensity, such as shocks, falls upon the buttocks or back, railway accidents, excessive bodily exercise, the lifting of heavy weights when the body is in an unfavorable position, etc. The disease may also be excited by the presence of chronic inflammatory processes or neoplastic growths of neighboring parts, which may pass to the meninges or excite a constant irritative action upon them; among these causes may be mentioned periosteitis, or caries of the vertebræ, chronic inflammation or sclerosis of the cord itself; tumors of every nature in or around the spinal cord, syphilis, and leprosy.

SYMPTOMS AND CLINICAL HISTORY.—The semeiology of chronic spinal meningitis has not been sufficiently studied, by reason of the fact that the disease is complicated with other affections which more or less effectually mask its symptoms. Its symptoms are, however, very similar to those of the acute form, but slower in development. In some cases the disease follows directly upon the acute form, in other cases several successive attacks of subacute meningitis develop gradually into the chronic form from want of proper precautions being taken during convalescence, but more often the disease is chronic from the very beginning, and insidious in its development. The first symptoms are usually abnormal sensations, as of weight in the lower limbs, with pain and stiffness in the back gradually increasing. This pain is at first not severe, it is never increased on pressure, but is aggra-

vated by motion of the vertebral column or by the alternate passage of a hot and a cold sponge along the spine; this is accompanied by excentric sensations, such as the feeling of a girdle round the trunk and boring or shooting pains down the extremities along the nerves arising from the affected region. The extremities feel heavy and weak, and a number of abnormal sensations, such as prickling, tingling, formication, numbness, etc., are present, varying in degree during changes in the barometric and thermometric conditions. These sensations are always more marked in the lower extremities. Along with these sensory disturbances symptoms of motor irritation also develop, but they are, as a rule, of subordinate importance; stiffness of the back and neck when the disease is situated high up; trembling of the extremities, sudden startings, muscular twitchings, jerking and involuntary drawing up or extension of the limbs, and gradual weakness, going on to paralysis, with loss of control over the extremities. The tendon and skin reflexes are sometimes normal, more often diminished or absent, rarely exaggerated. From the beginning there is always some disturbance of the functions of the rectum and bladder; the patient complains of costiveness, which only gives way to purgatives, and of difficulty in emptying the bladder, with some dribbling of the urine. The electrical irritability is at first diminished, and afterward altogether lost.

These symptoms fluctuate greatly, being worse in some cases one day than another, and in others being aggravated by the standing position; in the latter cases the accumulation of spinal fluid is probably excessive. In other cases, again, lying down on the back aggravates the symptoms; this is probably due to increase of the passive congestion occasioned by that position.

As time rolls on, the disease progresses; the pains and stiffness of the back become aggravated; the paræsthesia slowly gives way to anæsthesia, more or less complete; paralysis and atrophy succeed to the weakness of the limbs, so that the patient is bedridden. The bladder and rectum become completely paralyzed; cystitis and bed-sores are developed, and the patient dies of exhaustion or marasmus, unless he is sooner taken off by some acute complication.

Exceptionally an acute attack supervenes upon a chronic one, which has lasted for years, and rapidly puts an end to the case; but more frequently the disease drags on for years, with occasional temporary improvement and retrogression in the patient's condition, as described above. Occasionally, after a long lapse of time, the patients recover, with or without treatment; but, as a rule, this recovery is seldom altogether complete, and more or less impairment of function remains, in the form of atrophy or contracture of certain muscles or groups of muscles, etc. In very rare cases a complete and lasting cure is obtained.

The following cases will serve to illustrate the symptoms and course of the disease:

C. D——, white, male, aged thirty-seven, applied for treatment at the out-clinic department of Charity Hospital, in September, 1883, and was referred to my service. He gave the following history: By occupation he is a painter, but he has done no work for a year, on account of ill health. He is married, and of late years has been very temperate in his habits, not drinking at all, and using tobacco moderately; for ten years of his life, from the age of twenty-one to thirty-one, he drank rather freely, mostly whiskey of an inferior quality; he has never had syphilis; his family history shows no tendency to nervous or tubercular disease; he shows no sign of inherited syphilis, and, up to the beginning of his present ailment, he has been all his life in fair health. He has never had any symptoms of saturnine poisoning, either acute or chronic, and examination fails to reveal any of the signs of the toxic effect of this metal. About eighteen months previous to his admission to the hospital he felt, on getting up in the morning, a peculiar numbness and tingling feeling in both his lower extremities, and especially in his feet; this he attributed, however, to some abnormal position assumed during sleep, and went out to his work, as usual, returning only in the evening, when he felt altogether himself again. This feeling, however, returned on the following two or three mornings, accompanied by a dull, stiff sensation in the back, about the lumbar region; it became more and more persistent, so that by the end of a week it did not leave him during the whole day, and interfered with him in his work. He went to consult his physician, who told him he had taken cold, and gave him a plaster to apply to his back, a liniment to rub his extremities with, and a tonic to take internally, and said everything would be right in a few days. Not finding any relief after two weeks' treatment under his family physician, he was prevailed upon to consult another physician, under whose care he remained for several weeks, the symptoms becoming all the time aggravated, but not being of sufficient importance to force him to relinquish work as yet. About two months after he was first attacked he noticed that something was wrong with his urine, which he passed only in a small stream, and while at work a few drops would occasionally dribble from him. About that time also his bowels, which had always been very regular, became somewhat costive, and he was forced to make use of aperients frequently. Alarmed at this, he again changed medical advisers, and upon the advice of his newly chosen attendant refrained from work and remained at home, a great deal of his time in bed, for several weeks. Under this treatment he gradually improved, and at the end of that time was again able to return to his occupation. He remained better, however, only a short time, for the pains soon returned, but sufficiently severe this time to force him to rest of his own accord; the dribbling of urine became worse, and the numbness and tingling were continuous, even when he was in bed. After several weeks of rest he attempted to resume work, but could not. His legs felt heavy, he was unable to stand on them long, and the pain and stiffness in the back were worse, and had also invaded the legs; his urine continued to dribble, and he had to empty his bladder every hour or two during the day and night. This condition grew slowly worse up to the time of his admission into the hospital.

Upon my advice he remained as a patient in the hospital for two months, undergoing treatment, which consisted of mild galvanic applications to the spine, faradization of the extremities, and ten grains of potassium iodide, internally, four times a day, besides which he took, morning and evening, thirty drops of fluid extract of ergot and ten drops of tincture of belladonna. At the end of that time the following notes of his case were taken: Lancinating pains in back, extending from the middle dorsal region to the sacrum; pains extend around the abdomen and down the anterior and posterior aspects of the legs and thighs; stiffness of these regions; the pain and stiffness are increased by active motion of the spine and limbs, but there is no tenderness of the back, and no change in the symptoms is caused by motion of the body; his legs feel numb and heavy, and he occasionally suffers from formication; his gait is uncertain and tottering; tactile sensation is diminished in the lower extremities, but sensation to pain is about normal; the patellar reflex is a little exaggerated; electrical sensibility and irritability are diminished, but there is no reaction of degeneration. The muscles of the limbs are well developed and in a state of constant tension; the patient's general health is good, his appetite is good, body well nourished, and the cerebral functions are well performed. His upper extremities feel somewhat numb, but are otherwise normal; he suffers still from dribbling of the urine, and has frequent calls for micturition; he has occasionally passed his urine unconsciously in bed during sleep; the bowels are costive, requiring the frequent administration of purgatives and enemata; his abdomen is tense; the other inorganic functions are well performed.

At his own request the patient was discharged in this unimproved condition, and since then nothing has been heard of him.

A Case of Chronic Spinal Meningitis, of Six Months' duration, following an Acute Attack, resulting favorably after

Six Months' Treatment.—A. M——, white, male, aged twenty, a clerk by occupation, is well nourished, of temperate habits, never drinks, but smokes occasionally; he has indulged in sexual excesses for the past year. There is no hereditary history of disease; the patient has never had syphilis, but has had malarial intermittent fever frequently, lasting weeks at a time, during the last few years. Six months ago he fell from a horse and struck his back in the lumbar region; he was stunned, and remained unconscious for some time, and had to be carried home. He felt very sore in the back after the accident, but could move his legs and body, and had no difficulty with the bladder or rectum. After being taken home he was examined by his physician, who pronounced the injury trivial, no bone being broken or out of place, but advised his remaining in bed for some days.

The next day the patient, feeling better, got up and went about the house; two days after this he was taken with severe pain in the back, in the region where he had received the injury; the pain, he says, spread around the body like a belt, and shot down the thighs and legs; it was so severe that he had to go to bed. The next day a high fever developed, and the pain continued to increase, his back and lower limbs being also very much stiffened, so that he could not be moved without experiencing excruciating pains, and his urine had to be drawn. He was immediately put under treatment, and in a fortnight the fever had subsided, and the pains had diminished, but he had strange feelings, as of ants crawling, and numbness down the legs, which latter were almost completely paralyzed; he had lost control over his water, and his bowels were very much constipated. He remained pretty much in this condition until his admission into the ward for nervous diseases, of Charity Hospital, in December, 1885. He was immediately placed under treatment, large doses of bromide of potassium and chloral being given at first to relieve the pain, which had again become more acute in the back and lower limbs. In two or three weeks electricity was applied, when the reaction to the galvanic current was found diminished, but in the normal formula; the tendon reflexes were found subnormal; regular electrical applications were begun at that time, potassium iodide in five-grain doses, three times a day, was ordered, and the patient's bladder and bowels were attended to. Improvement was perceptible in a very short space of time, and six months after admission, in July, 1886, he was discharged, thoroughly cured, no untoward symptoms remaining. The patient was seen a few weeks ago, and it was ascertained that he had remained completely well since his discharge from the hospital.

DIAGNOSIS.—Chronic spinal meningitis is, as already mentioned, at times difficult to recognize, on account of the insidiousness of its beginning, and masked as it is by important complications; for its diagnosis we must rely on the pain and stiffness in the back, the paræsthesia of the extremities, and on the mildness and uniformity in distribution of the paresis, and the general absence of increased reflex action, of obstinate contractures, of atrophy, and of painful muscular jerkings, and on the modification of the symptoms generally caused by change in the position; all of these are characteristics of this disease and serve to differentiate it from myelitis, in which the paralysis and anæsthesia are severe, the contractures well marked and lasting, the muscular atrophy of paralyzed limbs noticeable, and the reflexes exaggerated, and in which the pains in the back and extremities, with stiffness of the spinal muscles, are absent.

From anterior poliomyelitis the characteristics of this disease, paralysis and atrophy, with no disturbance of sensibility, and absence of pain, are sufficient diagnostic signs.

Tabes dorsalis may be recognized by its accompanying fulgurating pains, ataxia, and disturbances of muscular sensibility. We must remember, however, that both affections are often combined.

Spinal irritation occurs in young women, as a rule, and is accompanied by symptoms of hysteria; its onset is sudden, and not always free from fever; there is hyperæsthesia of the spine, but no stiffness; there is tenderness over the spine rather than real pain, and the fluctuations in the intensity and character of the symptoms are marked. The severity of the subjective symptoms is also in striking contrast with the mildness of the objective appearances; there are no signs of organic disease of the cord; other signs of hysteria and of ovarian and uterine diseases are common.

PROGNOSIS.—The prognosis of chronic spinal meningitis is always serious; a cure is hard to obtain, and is generally exceptional in old and tedious cases; but improvement and cure have occurred even in what seemed at first hopeless cases, so that the prognosis must be guarded, and treatment should be persevered in for a long time, even in severe cases.

Sometimes, without apparent cause, the inflammation will become limited and the work of repair begin. The amount of improvement to be expected, then, depends essentially on the extent of the organization, calcification, or retraction of the effused material, and on its absorption. But even after the changes in the inflammatory products seem to be at an end, and the case has remained stationary for a long while, further improvement in the functions may occasionally be obtained in the course of time by means of judicious treatment.

Before making a prognosis the following conditions must be taken into account: The patient's age, constitution, and powers of resistance; the state of bodily nutrition; the causes which have brought on the disease, and the possibility of their removal; the amount of structural changes which have taken place in the spinal canal; the amount of myelitis and other complications, as shown by the intensity of the symptoms; and finally, the improvement brought about by previous treatment.

We must not, however, be too sanguine in our prognosis and lead the patient to expect too much.

TREATMENT.—In order to prevent the occurrence of this affection, great care should be exercised during convalescence from the acute form of the disease; all predisposing causes should be carefully looked after, and the exciting causes removed when possible.

As to the treatment proper, our attempts should be directed to the limitation of the disease, the relief of annoying symptoms, and the prevention of avoidable complications. For the first purpose, counter-irritation to the skin, especially along the spine, is useful; this is best accomplished by blistering, the application of tincture of iodine, turpentine, croton-oil, or other epispastics, and the use of dry cups. Antiphlogistics are rarely required, except in plethoric individuals with unusually severe symptoms, pointing to an invasion of the cerebral meninges; the same may be said of the wet cups and of profuse purgation for the purpose of bringing on intestinal derivation; at most, mild laxatives will be of use. Inwardly, iodine and the iodides in moderate doses, continued for a long while, with mercury in syphilitic cases; ergot and belladonna are often employed, but have been found of little or no benefit. Diuretics are of some utility in cases of abundant serous exudation. Warmth, externally, with stimulating frictions and massage to the affected limbs, has occasionally been serviceable.

To fulfil the second indication, an abundance of good, nourishing food, with an occasional stimulant, is required; tonics, such as quinine, iron, and the compound hypophosphites are necessary to combat the anæmia and debility which generally coexist with the disease.

For the relief of distressing symptoms, sedatives, such as opium and hyoscyamus, chloral, and the bromides are used for the quieting of the pain; for the same purpose, in obstinate cases, warm baths and baths of all sorts, wet packs, and alternate cold and warm water douches are also of service. A stay at one of various mineral springs will be of benefit in some cases to relieve the paresis and paræsthesia; stabile ascending and descending galvanic currents, of moderate intensity, and faradism to the affected muscles will also be of use in the same direction. For the rectal and bladder troubles, aperients, regularly administered, ergot, nux vomica, and electricity are of service.

SPINAL CORD DISEASES: CONGESTION OF THE CORD. Our actual knowledge regarding spinal congestion is very limited, and hypothetical statements that it is the basis of many nervous symptoms are unwarranted. The diseases in which it is uniformly found after death are those in which the patient has died in convulsions complicated by asphyxia, or in the early stages of myelitis. The only positive evidence that a spinal congestion has existed during life is the discovery of distended capillaries, accompanied by small capillary hæmorrhages. Without the latter the congestion found may have been a post-mortem occurrence, due to the position of the body on the back.

The *causes of active congestion* are excessive muscular exertion, violent sexual excesses, poisoning by strychnia, alcohol, and carbonic oxide, the sudden arrest of menstruation or the stoppage of hæmorrhage from piles, and possibly exposure to cold. Traumatism of the vertebræ, especially general concussion of the spine, such as occurs in railway injuries, probably causes active spinal hyperæmia, in a few cases examined capillary hæmorrhages having been found after death in the cord. It is probable that spinal congestion is usually localized in the lower half of the cord, though the entire organ may be affected. An active hyperæmia of the anterior cornua is the first occurrence in poliomyelitis anterior, and this is usually quite extensive, while the actual process of inflammatory degeneration is subsequently limited to a small area. The latter produces the permanent atrophic paralysis of infants; to the former must be ascribed the temporary paresis of the first stage of the disease, which is always more extensive than the permanent paralysis.

The causes of passive congestion are the same as those producing this effect in the brain or other organs (*q.v.*).

The *symptoms of spinal congestion* are a sensation of weight and fatigue in the legs and back, increased by any effort, so that continued exertion is impossible; pains, numbness, formication, and sensations of heat and cold, with increased susceptibility to changes of temperature and to pain and touch in the extremities; weakness, but not paralysis, in the entire muscular system, attended by an increase of reflex excitability; a diminution of sexual power; and a diminution of control over the bladder and rectum not sufficient to be termed incontinence. Any symptoms more serious than these, such as severe tearing pains in the back and general hyperæsthesia; or such as girdle sensations, incontinence, and actual paralysis, must be ascribed to congestion of the spinal meninges as well as of the cord, or to disturbances of a grave nutritive kind initial to an actual myelitis. These symptoms are always bilateral, and usually more marked in the lower half of the body, although the arms may become involved. They usually come on suddenly after some known cause; but occasionally a chronic congestion is suspected, which lasts for months, and is attended by symptoms of neurasthenia.

The *diagnosis of spinal congestion* is an uncertain one. When symptoms such as those described appear, and do not go on to more serious conditions, but gradually pass off, and an adequate cause can be found, the diagnosis can be made. If, however, serious symptoms of myelitis ensue, it must be admitted that the disease was myelitis from the outset, and not a simple hyperæmia. A long duration of symptoms of spinal congestion points rather to the existence of capillary hæmorrhages, attended by small foci of inflammatory degeneration, or to nutritive changes in the spinal cord.

The *prognosis* should always be reserved, in view of the uncertainty of diagnosis and the possibility of myelitis.

The *treatment* should consist of absolute rest in bed, in a prone position; the application of cool cloths, wet with an evaporating lotion, to the spine, or an ice-bag or the ether spray; saline purgatives; and full doses of ergot with small doses of belladonna.

M. Allen Starr.

SPINAL CORD DISEASES: HÆMORRHAGE IN THE CORD. Synonyms: Hæmatomyelia; spinal apoplexy.

Hæmorrhage in the spinal cord is very rare in comparison with hæmorrhage in the brain. When it occurs it is usually of small extent. This is not extraordinary when the size of the organ and the firmness of its connective-tissue sheath, and the low pressure in the spinal arteries, are considered. As a rule, the clot in the spinal cord is long and narrow. It destroys a considerable part of the cord at one segment, and extends into the segments above and below, injuring these to a less extent. The clot is usually found in the gray matter of the cord, most frequently in the anterior horns, then in the posterior horns, and most rarely in the white columns. Sometimes the surface of the cord is broken and the blood infiltrates the pia mater. As the patient rarely dies at once of hæmorrhage the clot is usually found in a state of decomposition, and the cord around it is infiltrated with blood-cells, pigment-granules, and hæmatin crystals. If the hæmorrhage is capillary—as sometimes occurs—it is detected by the presence of pigment and crystals among the degenerated spinal elements. Around the clot the spinal cord is usually found in a state of softening, which is red in recent cases, and white when the process has been a long one. At a post-mortem the question sometimes arises whether the condition found is a myelitis with secondary hæmorrhage, or a hæmorrhage with secondary myelitis. In the former case the microscopic examination shows a greater preponderance of granular corpuscles, a greater degree of degeneration in the nerve-cells, and a greater extent of connective-tissue growth. Secondary degenerations upward and downward from the segment destroyed, and secondary degenerations in the motor nerves from the segment affected to the muscles, are observed after spinal hæmorrhage as after myelitis. The meninges are rarely involved.

ETIOLOGY.—Spinal hæmorrhage is met with in males more frequently than in females, and in youth and middle age most often. The predisposing causes are chronic changes in the general arterial system, and inflammatory congestion or myelitis of the spinal cord. The exciting causes are the same as those of spinal congestion (*q.v.*), to which must be added the sudden exposure to a marked change of atmospheric pressure, to which workers in caissons and divers are exposed. The so-called caisson-disease is a congestion of the spinal cord (and brain ?) attended by minute hæmorrhages and secondary subacute myelitis.

SYMPTOMS.—Very rarely the symptoms of spinal congestion precede those of hæmorrhage. As a rule, the symptoms begin very suddenly, and the patient is seized in a moment with complete paraplegia and intense pain in the back at the level of the hæmorrhage. When premonitory symptoms have existed for a few days it is probable that the case is one of acute myelitis. A spinal apoplexy usually comes without any warning, after a sudden effort. The extent of the paralysis depends upon the level of the lesion. (See Local Lesions.) If in the lumbar or dorsal region, the lower half of the body only is involved; if in the cervical region, the arms are affected as well. The hæmorrhage is rarely so very limited as to affect one extremity only, but it is not infrequently the case that the symptoms are more marked on one side. The paralysis is total, no voluntary motion is possible, the limbs are relaxed and never rigid. The muscles do not atrophy or present any change in the electric reactions, excepting those which are supplied with nerves from the segment which is destroyed by the hæmorrhage. The condition of the reflex action depends upon the seat of the lesion, it is suspended at the level of the hæmorrhage,

and increased in the segments below it. The bladder and rectum are uniformly paralyzed, and various forms of incontinence of urine and fæces result, dependent upon the seat of the lesion. If this is high up in the cord, the viscus may empty itself occasionally, as the need arises, unconsciously to the patient and independent of his effort or control. If the lesion is low down (below the eleventh dorsal segment), there is usually retention of urine and fæces, or complete relaxation of the sphincters. Vasomotor paralysis accompanies the voluntary paralysis, and results in cyanosis and coldness of the paralyzed limbs, and predisposes the parts to the development of bed-sores. The latter appear, very soon after the hæmorrhage, on the prominent parts of the body which are subjected to pressure; voluntary movements to relieve such pressure, or reflex movements for the same purpose, being impossible on account of the lack of power and of sensation, for complete anæsthesia and analgesia exist in the paralyzed limbs from the outset. Pain in the back, which occurs at the time of hæmorrhage, does not usually persist. The danger in these cases is from the occurrence of bed-sores, or of cystitis, and consequent infection from these sources, with the development of septic fever. If the hæmorrhage involves the respiratory centres in the upper cervical region, sudden death takes place. This is rare.

The symptoms described are those of a severe hæmorrhage, sufficient to destroy one or more segments of the cord; if the clot is a small one, however, they may be more limited and less serious, partial anæsthesia and localized paralysis, with atrophy, being the result. This, however, is the exception. Capillary hæmorrhages give rise to wide-spread symptoms, which so closely resemble those of diffuse myelitis that differential diagnosis is impossible.

The *prognosis* is very bad in spinal apoplexy, for a destruction of the spinal elements cannot be recovered from. The patients either die suddenly, or die of complications, or linger on for months with all the symptoms of chronic myelitis. In the lighter cases they may recover sufficiently to get about, but some evidences of the hæmorrhage in the form of local paralysis or areas of anæsthesia, always remain.

The *diagnosis* is usually easy, the sudden onset of total paraplegia being characteristic. In meningeal hæmorrhage the paralysis is less marked than the spasms, and anæsthesia is rare. In poliomyelitis anterior there is marked constitutional disturbance, with fever, before the paralysis begins, and anæsthesia is not present. In acute central myelitis the onset is more gradual, the symptoms develop successively, they extend gradually to other parts, and fever is usual.

Treatment cannot reach the disease, and hence resolves itself into a care of the patient, and such measures as are used in the management of a case of chronic myelitis.

M. Allen Starr.

SPINAL CORD DISEASES: HYPERTROPHIC SPINAL PACHYMENINGITIS. Definition. — Hypertrophic spinal pachymeningitis is a chronic inflammation of the spinal dura mater, limited in longitudinal extent, and more generally affecting the region of the cervical enlargement, but occasionally found in the dorsal region or lumbar portion of the cord. This inflammation gives rise to thickening and hypertrophy of the dura mater, and secondarily implicates the arachnoid and pia mater, causing their adherence to the former membrane. The hypertrophied membranes, by pressure, produce a secondary transverse myelitis and atrophy of the nerve-roots arising from the affected region.

The cervical form of this affection, though mentioned by others previously, has been thoroughly studied and described by Charcot and his pupil Jeoffroy, from whom the greater part of our information is obtained.

Pathological Anatomy.—The primary and chief lesions of pachymeningitis spinalis hypertrophica are found in the spinal meninges, and particularly in the dura mater. On opening the spinal canal the marrow at the affected part is found to consist of a large fusiform tumor, filling the whole canal, and adherent or not to the vertebral ligaments. Upon section this tumor is found to be composed mostly of the hypertrophied dura mater, to which the other membranes, whether affected or not, are adherent, inclosing and making pressure on the spinal cord and nerve-roots. This tumor consists of a hard, fibrous, and dense tissue, arranged in concentric layers, and has for its origin an inflammation of the internal surface of the dura mater with proliferation of the connective tissue.

As secondary lesions, we find the spinal cord compressed by this hypertrophied tissue as in a ring, and showing signs of transverse myelitis with ascending degeneration of the posterior columns. This transverse myelitis is caused by the compression of the cord, but it is believed in some instances to be due to extension of the inflammation from the meninges. The nerve-roots arising from the affected region are also compressed, pale, and atrophied, but the nerves beyond have been

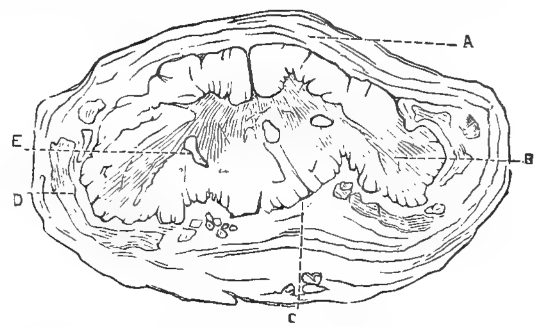

Fig. 3646.—Hypertrophic Cervical Pachymeningitis. A, Hypertrophied dura mater; B, nerve-roots passing through the thickened meninges; C, pia mater adherent to dura mater; D, lesions of chronic myelitis; E, section of two newly formed canals in the gray substance.

found normal. The muscles supplied by the affected nerves show signs of atrophic degeneration.

Pulmonary tuberculosis or cystitis, with bed-sores, is generally found as the cause of death.

Etiology.—This is a disease of adult life. No predisposing cause is known, though syphilis and alcoholism are supposed to act as such, for a number of the observed cases were seen in inebriates or syphilitic persons.

Exposure to cold and dampness is the only known exciting cause, though in some instances the inflammation may have extended from a previous perimeningitis, and in a case observed by me, and here related, a fall on the back of the neck seems to have acted as the exciting cause of the pachymeningitis.

Symptoms and Clinical History.—Hypertrophic spinal pachymeningitis may be divided into two distinct stages or periods: The irritative or meningitic period, and the paralytic and atrophic, or myelitic, period.

In this article we shall describe the cervical variety of the disease, which is the most common, and the only one which has been thoroughly observed.

Irritative Period.—This affection, which is generally insidious, first shows itself in one of two forms, the central and the peripheral. The predominating symptoms in the central variety are pain and stiffness in the back of the neck, radiating to the occiput and head. The pain, at first mild in character and resembling that of wry-neck, presents distinct periods of exacerbation, and is generally worse at night; in a short time it becomes constant, and is always aggravated by motion of the neck, rarely by pressure upon the spinous processes. Along the limbs dull pains of a rheumatic character are then experienced, and in the joints sharper shooting pains, at times increased by pressure. The joints remain normal as regards swelling and redness. In the fingers and hands there are numbness, formication, and a greater or less diminution of tactile sensibility. These peripheral pains are generally more marked on one side than on the other: they are the first to show themselves in the peripheral form of the disease.

Spinal Cord.

Later on, the pains extend along the spine to the lumbar region and to the lower extremities, occasionally more on one side than on the other; they increase to such a degree that the patient is forced to give up his occupation, and at times to betake himself to bed. Nausea and vomiting are frequent at this stage, and seem to further weaken the patient.

This period lasts from two or three to five or six months, when, in some cases, there is a period of comparative improvement, and in others the second period is ushered in.

Second or Paralytic Period.—In this period, also known as the chronic period, paralysis usually appears in one of the upper extremities, as a rule in the one in which the pains were first or more acutely felt, but it soon extends to the other extremity. This paralysis, which progresses with more or less rapidity, is always accompanied by atrophy and diminution of electrical excitability. The atrophy, in the majority of instances, is limited to the pronators and flexors of the hands, and all the muscles supplied by the ulnar and median nerve, or is more marked in them than in the supinators, extensors, and other muscles supplied by the musculo-spiral nerve. This may be due to the fact that the lower portion of the cervical enlargement, from which the ulnar and median nerves arise, is more often implicated than the upper portion of the enlargement, from which arises the musculo-spiral nerve. In the non-atrophied muscles contracture sets in early, giving rise to peculiar deformities, the more common of which is the claw, or preacher's hand, in which the hand is extended at the wrist, the third phalanges extended and the two first remaining flexed. This deformity, though not found in this affection only, is, however, one of its marked characteristics.

The paralysis next invades the lower extremities, but in these atrophy seldom or never occurs; at times, however, the muscles of the lower extremities, as well as those of the trunk, tongue, and lips, all become atrophied. Paralysis of the muscles of respiration, bringing the case to a speedy fatal termination, rarely occurs.

The sensory symptoms have not been so well studied, and do not seem to be as constant; there is first paræsthesia, followed later by anæsthesia or hyperæsthesia, or there is anæsthesia of one extremity and hyperæsthesia of the other.

Trophic changes have also been observed, such as itching, dryness, and desquamation of the skin over the affected regions, or the development of a vesicular or bulbous eruption over the affected hands and arms. Acute eschars form at times on the buttocks, over the sacrum, on the heels, or in the mucous membrane of the bladder, giving rise to a bad form of cystitis. The bladder and rectum are paralyzed late in the course of the affection.

Occasionally convulsive motions of the limbs, amounting at times to spinal epilepsy, have been observed. The reflexes are exaggerated in some cases, in others they are not affected.

When the dorsal region is affected, we have the atrophy, paralysis, and trophic changes affecting the trunk; early paralysis of the lower extremity, and complete immobility of the upper extremities.

When the lumbar region is alone affected, the symptoms are limited to the parts supplied from this portion of the cord.

The following case illustrates the course of pachymeningitis hypertrophica spinalis ending in recovery:

E. F——, white, male, aged forty-five, single, laborer, intemperate in habits, gives no family history of disease, but had syphilis twenty years ago. He was admitted into the ward for nervous diseases of Charity Hospital, on May 2, 1885, with the following history: One year before admission, the patient was thrown from a horse and fell on the back of his head and neck; he was able to pick himself up after the accident, and, though he suffered greatly with pain in the neck and head, returned home on foot, a distance of several miles; he was confined to his room for several weeks, suffering from shooting intermittent pains in the back of the neck and head; the neck was very stiff, and the least motion or touch on the parts gave rise to excruciating pains. Accompanying this, and developing shortly after, were numb feelings and occasional shooting pains extending down the arms and hands, especially on the left side, the elbow and wrist were very tender and painful, making it almost impossible for him to raise his arm. About twelve weeks after the injury the pains in the neck, head, and arm had greatly increased, and he could make little or no use of his upper extremities, which were stiff and useless. About this time the muscles of the hand and forearm began to waste, and his hand was drawn back over the arm at the wrist, the fingers being extended; he began also to feel weak and stiff in the legs, and to be troubled with retention of urine and costiveness; the pains in the legs, however, were never so great that he could not move about, though he was incapacitated for work.

Upon admission his general condition was found to be good; there were no general symptoms; his arms and hands were almost completely paralyzed, the left more so than the right; there was atrophy of the pronators and flexors of the hands and fingers, and of the biceps; the extensors of the upper extremities and supinators were contracted. The deltoids were normal. He had the typical claw hands, and had to be fed, being unable to bring the food to his mouth. The lower extremities were well developed, but he complained of weakness causing tremor and stiffness; his gait, when walking, resembled that of a patient with spastic paralysis. The bladder was somewhat affected, the patient having to empty it almost hourly; the bowels were costive, only acting when stimulated. The muscles of the neck and upper part of back were stiffened. Sensation, both general and tactile, was greatly diminished in the upper extremities, but the neuralgic pains in the head, neck, and arm had almost completely disappeared, coming on only at rare intervals; sensation in the lower extremities was a little below normal. The patellar tendon reflex was exaggerated, and there was marked ankle clonus in both legs. The faradic and galvanic irritability was present, but greatly diminished in the upper extremities, though almost normal in the lower extremities.

The patient was put on tonic treatment, and a mixture of the bromide and iodide of potassium, grs. xv. of the former and grs. x. of the latter, given three times daily; dry friction was made over the extremities, and the continuous current was applied to the back and arm, the faradic to the lower extremities. At the end of six months there was marked improvement, the patient felt stronger and could walk better, though the legs still felt stiff. He could also flex his fingers almost to the palm of his hand, and bring the right hand to within two inches of his mouth, and thus feed himself; the pain in the back of the neck and limbs had disappeared, and, subjectively, sensation in the upper extremities was very much improved. Slight response in the atrophic muscles could be obtained with a twenty-four-cell bichromate of potash galvanic battery; the hands and forearms looked a little fuller. The control over the bladder was nearly normal, the viscus being emptied only three or four times during the night, and about twice as often in the daytime; the bowels acted without assistance. His condition continued to improve until December, 1886, when he left for Cincinnati, having obtained some occupation in that place as keeper in a warehouse. When he left the hospital he could be on his feet all day; sensation was quite normal, and, aside from a slight stiffness in the leg, he felt no untoward symptom in walking. He could bring his hands to his mouth and shut the fingers, though he could not hold a weight.

This case, on account of the rapid improvement and amelioration of the worst symptoms, should, in our estimation, be classed as a case of cure.

Course and Termination.—The course of the disease is generally progressive, but the affection may last for a number of years. The termination is generally fatal, the more rapid cases terminating fatally in about five years, the slower ones lasting from fifteen to twenty years. Occasionally cases, like the one just reported, re-

cover. Charcot has reported a case, much more advanced than ours, in which the same happy termination took place.

DIAGNOSIS.—This affection may in its initial stage be confounded with torticollis. The fact that the whole neck is implicated, instead of one side, and the presence of radiating pains in the upper extremities, will, however, suffice for a diagnosis.

Hysteria is to be distinguished from the initial stage of the peripheral form by the other symptoms pointing to that hybrid affection.

Progressive muscular atrophy is to be differentiated by the absence of painful symptoms, the more limited atrophies, and the difference in its seat, and by the absence of the claw-hand.

Myelitis can be distinguished only by the history of the case.

Pott's disease of the vertebræ can usually be diagnosticated by its history.

PROGNOSIS.—The prognosis of pachymeningitis, as a rule, is unfavorable; but, from what has been said above, a cure may be hoped for in a few cases, even after the symptoms denoting the secondary involvement of the nerve-roots and cord have appeared. In a number of cases, however, when the symptoms are meningitic only, much can be hoped for with appropriate treatment.

TREATMENT.—In the first period of the affection, in robust and plethoric patients, antiphlogistic measures may be resorted to; but with the majority of cases the treatment must be symptomatic and carried out on the same general principles as that for other forms of meningitis.

Sedatives, such as opium, but preferably chloral hydrate and bromide of potassium, to relieve pain; belladonna and ergot, to limit the extent of the inflammatory processes; iodine and the iodides, to favor the reabsorption of the exudate material, and to diminish connective-tissue proliferation, are called for.

The use of the actual cautery to the spinal column, recommended by Jeoffroy and Charcot; electricity, especially the galvanic current, to the spine, and hydrotherapy are all at times indicated.

In the second stage, the continued use of iodide of potassium in large doses; of tonics, to keep up the patient's strength; counter-irritants, especially the actual cautery, to the spine; electricity, both galvanic and faradic; massage, etc., are of service.

SPINAL CORD DISEASES: INJURIES AND WOUNDS. Injuries of the spinal cord and membranes were studied and described by Sir Astley Cooper and other surgeons of the last century with considerable minuteness and care. Microscopic study and the investigations of neurologists have so supplemented clinical study that the pathology of diseases of the cord has been almost entirely rewritten within a short term of years, and these investigations are not to be left out of account in considering the surgical diseases of the nervous system. Part, at least, of the changes resulting from injuries to the cord and membranes are identical with those found in disease. An intelligent understanding of their nature can, therefore, be obtained only through acquaintance with recent important investigations on the functional and organic diseases of the spinal cord. We cannot here enter into the pathological and normal anatomy as studied in disease and in experiments upon animals. This subject has been fully discussed in a preceding article.

It is sufficient to call attention to the importance of these investigations, a knowledge of which is at the foundation of a proper understanding of the effect of injuries upon this part of the nervous system. Not only are the local structural changes often the same in disease and in the results of traumatism, but secondary effects appearing in remote organs are frequently identical, whatever the primary lesion. It is evident that much of the discussion of spinal injuries in surgical treatises is based upon clinical and not upon pathological data. It is also true that writers of eminence have treated this subject, which is often a medico-legal one, almost in a controversial spirit, drawing opposite conclusions in some instances from the same clinical evidence.

Erichsen has collated numerous cases from the published works of Cooper, Bell, Abercrombie, Brodie, and others, which he has added to his own in illustrating certain ideas on spinal "concussion." Page, on the other hand, has drawn largely from the same sources, and even from Erichsen's own cases, to support views quite opposite. Neither writer utilizes to the full the best results of modern investigation on the pathology of the cord. We are therefore left with the impression that much of this discussion is but threshing old straw, so far as scientific interest is concerned, however much importance may attach to it in the eyes of lawyers and claim-agents. It is well, nevertheless, for all medical men who are subject to calls for expert testimony, and especially in railway practice, to be conversant with such works as that of Page.

CAUSES.—The spinal cord is exceedingly well guarded from all external violence. Axially situated with reference to all bodily movements, protected by its semi-rigid bony and ligamentous canal and by thick cushions of muscles, there would seem to be little liability of its receiving mechanical injury except in destructive accidents to the vertebræ. On the other hand, the fragile and soft texture of the gray matter of the cord makes it more vulnerable than most tissues. Even the white fibrous columns, which surround and inclose the gray matter, are comparatively frail and intolerant of interference, so that slight causes, when persistent, may set up serious alterations of structure. It is not to be inferred that complete recovery cannot take place after considerable violence has been done to the cord-substance as well as the membranes, provided the source of irritation or compression has been completely removed. This *must be* true of slight lacerations, since it has been observed clinically in actual wounds of the cord-substance.

Meryon describes a case of incised wound in a lad, fifteen years of age, in which the spinal canal was penetrated by a knife between the tenth and eleventh dorsal vertebræ, and the cord was partially divided, so that there was escape of spinal fluid and paralysis of parts of the body below. The left leg and thigh were completely paralyzed, and it was inferred—without doubt correctly—that the cord had been partially severed. The patient, notwithstanding, recovered entirely in two months. Many such cases of complete or partial recovery have been recorded, which show that reparation is possible in the nerve-structure under favorable circumstances. It cannot be asserted that this is usual in penetrating wounds; but in simple injuries, such as laceration of membranes, contusion, or "concussion" of the cord, and small circumscribed hæmorrhages, even when accompanied by paraplegia, perfect recovery may often be expected.

Blows upon the spinal column, without producing any fracture or displacement of the vertebræ, may cause symptoms ranging from slight neuralgia to complete paraplegia. This is the simplest type of injury to the spinal cord or membranes, and is analogous to similar injuries to the brain from blows upon the skull. It cannot be said that this is very common in the typical form.

In "Guy's Hospital Reports" for 1856 is described the case of a boy who was struck in the back with the fist, and shortly afterward developed pain in the extremities, difficult urination, spasm of the muscles, and other signs of spinal irritation. The patient soon died, and the autopsy showed the spinal canal nearly filled with pus. It is so unusual for traumatic arachnitis to take a suppura-

tive form, when no external wound and consequent sepsis has occurred, that some doubt may be entertained in this case as to whether the blow was the real cause of the disease.

Genert describes the case of a woman, forty years of age, who received a blow upon the back, which was followed by pain and loss of voluntary motion, beginning in the right foot, and gradually extending over the body, with spasmodic contractions and ultimate death. The autopsy showed the posterior columns softened and inflamed in the lumbar enlargement.

By far the greater number of injuries to the spinal cord are the result of *indirect violence.*

Falls which produce no injury to the bones either of the extremities or of the spinal column are often followed by symptoms indicating functional or structural derangement of the spinal cord. Many observers have noticed the fact that the spine usually escapes injury when the extremities suffer, as in fractures and dislocations.

It may be that some cases of spinal irritation pass unobserved on account of the graver trouble which is present. The enforced rest involved in the treatment also has a most favorable influence upon the speedy recovery of such cases.

Erichsen inclines to the theory that the traumatism in one part of the body breaks the force of the blow received, and thus diminishes the violence of its effect upon the spine. He adduces the statement of watchmakers that, when a watch falls to the ground, "if the glass be broken, the works are rarely damaged ; if the glass escape unbroken, the jar of the fall will usually be found to have stopped the movement." As an illustration rather than an exact analogy, this serves to explain how the sacrifice of one member may save the integrity of another.

A blind man was admitted to my department, in Mercy Hospital, in 1880, who had walked out of a third-story window and struck upon his feet, fracturing both his thighs. It is easy to believe that, had the femurs not broken under the tremendous impact of the body, the contents of the spinal canal might have suffered from the shock.

Extreme bending or *twisting* of the spinal column is responsible for a large number of cases of irritation of the cord.

Slight injuries to the vertebræ, to the intervertebral disks, or to the ligaments may, just as in the case of other articulations, extend somewhat to surrounding parts, and give rise to localized meningitis and thickening.

Page has pointed out that irritation of the posterior common ligament cannot occur without risk of injury to the spinal membranes, not so much by their being implicated at the time of injury as by extension of the inflammation to adjacent parts. The ligamenta subflava are also, as he observes, in such immediate relation with the meningo-rachidian veins that laceration of their substance will produce rupture of the veins and extravasation of blood into the spinal canal, a state of affairs which may cause immediate impairment of function, followed by inflammation and degeneration of the cord.

Railway accidents are the cause of a large number of alleged injuries to the spinal cord. This is universally known outside the profession, as well as in it, and its importance lies chiefly in the number of suits for damages against railway companies which arise from it. Erichsen declares that injuries received in railway accidents are not essentially different from those occurring elsewhere. That they are more common on railways is probably true ; but it is also a fact that such injuries are sometimes much exaggerated by patients from mercenary motives.

Page, whose treatise is written with the intent to minimize the importance of this class of cases, nevertheless gives detailed histories of 250 cases occurring in his own private and hospital practice, and intimates that he could furnish records of at least 500 from the same source. Many of the cases cited are fraudulent. Yet the fact seems evident that they are very numerous in railway surgery.

Symptoms.—The signs of injury to the cord are to be referred chiefly to perverted or impaired innervation of the parts below the lesion.

Disorders of sensation are among the earliest symptoms.

Pain, which is for the most part absent locally, is often felt in the form of neuralgias of the parts supplied by the spinal nerves below the point of injury. These pains are usually radiating and intermittent, and are often aggravated by movements. Usually they precede paralysis where the latter occurs.

Local tenderness is a symptom so inconstant as to be of little importance. When present, it may point to injury of the bones or spinal muscles.

Anæsthesia and *analgesia* are common symptoms of spinal injuries involving either the sensory nerve-roots or the anterior columns. Complete loss of sensation may come on when there is paraplegia.

Hyperæsthesia is also a prominent symptom in a certain number of cases, particularly in the earlier stages. Even when there is total paralysis of motion there may be exalted sensibility of the skin. A light touch upon the legs or genital organs may produce the sensation of severe cutting or burning.

Disordered spinal reflexes are closely allied to sensory disturbances, and perhaps to some extent dependent upon them. Exalted action may coexist with, and depend upon, increased sensibility. The so-called "spastic paralysis" is a form of paraplegia in which the limbs are suddenly and violently flexed or extended when touched, quite independently of the patient's control. The jerking may be so violent as to cause pain and visibly jar the bed. It has been likened to the snapping of a pocket-knife. The paraplegia of disease—as of Pott's disease—is sometimes of this form.

Continuous or *tonic muscular spasm* is a constant and early symptom of the milder forms of spinal irritation, especially those affecting the anterior columns. This is probably due to reflex irritation.

Priapism, which is also common in injuries of the spine, may possibly be due to reflex action, or, as Agnew suggests, to paralysis of the sympathetic fibres within the cord. Bramwell attributes this symptom to irritation of the excitor fibres which pass down from the brain. Priapism is said by some authors to result only from injuries high up in the cord ; but Lidell quotes a case wherein it occurred from injury at the level of the tenth dorsal vertebra. Surgeon Tripler, U. S. A., describes a case from an injury at the junction of the dorsal and lumbar vertebræ.

Impairment of reflexes is an important symptom of another class of cases which usually are accompanied by more or less analgesia and anæsthesia. Knee-jerk and ankle-clonus are very frequently entirely wanting, but the cremasteric and epigastric reflexes are also abolished. Such cases are apt to show more or less inco-ordination of muscular action, and consequent impairment of gait and movement.

Motor derangements are present in most cases of spinal irritation. Inability to empty the bladder and rectum are common and early signs, with or without paralysis of the extremities.

Partial or complete *paraplegia* is the most characteristic sign of injury to the cord, whether from wounds, fractures of the vertebræ, or simple concussion.

The loss of voluntary motion may be of all degrees, and with or without muscular rigidity or lack of co-ordination.

Trophic disorders are seldom wanting in the paralyzed parts. Muscular atrophy is usually seen after a certain time has passed. Among trophic disorders may also be noted the "neuropathic eschars" (Brown-Séquard) which form upon the sacral region in cases of paraplegia. These sometimes appear so early after injuries of the spine that they can hardly be due to pressure alone, like ordinary bed-sores. They may also appear in other localities. Conant describes several cases in which they were seen upon the inner aspect of the thighs. Stephen Smith reports a case of injury to the spinal cord, followed by

neuropathic sphacelus upon the heel and ball of the great toe.

Another form of trophic disorder is the remarkable affection of the joints first observed in locomotor ataxia by Charcot, and called by him "arthropathy." The limbs become suddenly swollen to an immense size, and are almost as suddenly reduced, after which the joints and bursæ are found distended with fluid. Remak and Patruban observed similar joint-affections in the disease called progressive muscular atrophy. Sir William Gull described a case of "concussion of the spine" in which there was paraplegia accompanied by great enlargement and redness of the wrists and ankles, lasting four months.

Excessive sweating and increase or diminution of temperature over limited areas of the skin are probably the results of vaso-motor derangements through the sympathetic fibres within the spinal cord.

Cerebral and functional derangements largely predominate over the symptoms of spinal irritation in a certain class of cases, particularly those resulting from railway accidents. While there may be a slight basis of spinal trouble, the chief symptoms in many of these cases are those of nervous prostration from fright and worry; and the trouble, so far as it can be located at all, is in the brain, and not in the spinal cord. Many of these cases need the attention, not of a surgeon, but of a neurologist.

A misleading impression has gotten abroad, not without some authority, that these symptoms, clearly of the mind, or at least cerebral, are the ultimate results of spinal concussion. There is nothing in the pathology of the cord, as now known, that will support this view, however. It is more scientific to separate carefully those symptoms which are spinal from those which are cerebral, and much controversy can in the future be avoided by keeping this distinction in view. As to "railway spine," it has very justly been said that "railway brain" would be a more appropriate designation. Most of the symptoms alleged in these cases are not those of spinal origin. It is "safer and wiser to separate and differentiate those symptoms which are cerebral or psychical from those which can only find an explanation in some actual lesion of the spinal cord or of the nerves which are given off from it."

Headache, loss of memory, sleeplessness, melancholia, and "lack of business aptitude" are the symptoms most often spoken of in this relation. Impairment of vision does, however, occur in slight injuries of the cord. This is probably due to simple atrophy of the optic nerve and hyperæmia of the disk (Albutt, Wharton Jones).

Temporary impotence is not rarely an accompaniment of injuries of this class. Irregular attacks of nausea from functional derangement are also quite common.

The PATHOLOGY of injuries of the cord is to be understood only by keeping in mind the various columns of degeneration which have been mapped out by pathological study. An understanding of the various functional disorders which may simulate organic diseases of the cord, and of the curious and interesting subject of spinal reflexes, is also a requisite for a thorough comprehension of the effects of injuries. These matters will be found adequately discussed elsewhere in this volume, and still more fully in the works of Bramwell, Gower, and other writers.

The pathology of injuries is not wholly dissimilar from that of diseases of the spinal cord. In at least one affection—tabes dorsalis or locomotor ataxy—there is evidence that idiopathic and traumatic cases may be identical in kind. Leyden maintained this view in 1863, and was corroborated by Topinard (1866). Petit (1879) also tries to show that ataxy may be of traumatic origin. Page, while not absolutely denying the possibility of this being true, holds it to be improbable, since it is a disease of definite tracts, and it is not likely that these alone would be injured in case of an accident. Gower thinks this might result from the whole cord being at first involved, and all parts except the posterior columns recovering, leaving the latter degenerated. It is not to be forgotten that there may be syphilis back of such cases.

In place of the term "concussion of the spine," it will be better, so far as possible, to use more definite terms. This we can now do with considerable certainty when speaking of many of the morbid conditions which result from injury of the cord and membranes.

Intraspinal hæmorrhage, following slight lacerations of the ligaments or nerve-substance, is the starting-point of many slight impairments of function as well as many grave ones.

The close relation of the meningo-rachidian veins to the fibres of the ligamenta subflava makes it probable that they would be torn when the latter are ruptured. Hæmorrhage may be slight in quantity, so as to form mere ecchymoses upon the surface of the cord or membranes, or it may fill the spinal canal and produce fatal compression. The signs of compression can hardly appear as quickly as in the case of a fracture, and in many cases some hours or days elapse before serious impairment of function is noticed. Lidell believes the diagnostic sign of hæmorrhage to be the fact that the symptoms begin at a point low down and gradually ascend as the level of the blood rises in the spinal canal.

Brown-Séquard asserts that hæmorrhage within the substance of the cord is distinguished from accumulations around it by the absence of convulsions, and the gradually diminished sensation in parts below. Hæmorrhage around the cord compresses the roots of the spinal nerves, giving rise to convulsions as well as paralysis of motion.

Traumatic meningitis of a subacute form is a common result of slight injuries of the spine. Some thickening of the membranes occurs when the irritation is persistent, and, doubtless, compression of the cord occurs in this way without actual inflammation of its substance, or myelitis. Serous or purulent exudation into the arachnoid, and congestion of the pia mater, with occasional ulceration and perforation of the membranes, are the principal features of this affection.

Traumatic myelitis and meningo-myelitis of traumatic origin may be limited to the region where the injury has been received, or may extend so as to involve adjacent columns. Extension upward or downward to any great distance is not usual. The inflammation is of a subacute or chronic type, and quite commonly ends in complete resolution, with disappearance of the paralysis or other symptoms. A few cases end fatally from paraplegia and final exhaustion. Gower saw a case of slow paralysis following a railway injury which ended fatally, and in which the autopsy showed the gray matter of the cord studded with numerous minute foci of chronic inflammation.

Pure concussion, if it exist as a pathological state, may be defined as a "stunned" condition of the cord, which is assumed to have undergone some form of molecular derangement too slight to reveal itself in the gross appearances, yet sufficient to cause functional derangement. There are well-attested cases in which paraplegia and death have occurred from supposed injury to the spinal cord, in which, on post-mortem examination, no injury to the nervous substance could be detected. Yet, if we remember the liability to overlook cerebral injuries, and even clots in the substance of the cord itself, we cannot always assert with positiveness that some important lesion may not have escaped notice. It is only within recent years, and in a very few hospitals, that post-mortem examinations have been conducted exhaustively. Lidell describes a case of fatal injury to the cord, in which the autopsy at first showed apparently no lesion in the cord until, upon careful section, a globular clot was found at one point, in its very centre, which had so compressed its substance as to cause death.

TREATMENT.—The treatment of injuries of the cord and membranes calls for rest, not merely physical but mental, and complete immunity from care and worry. The reason for this is that all parts of the nervous system suffer in these cases, and all parts respond unfavorably when any cause of nervous excitation exists. There are many cases in which the spinal symptoms alone are of importance, and others in which mental and psychical disturbances seem to be the main features, but all alike

receive benefit from a somewhat prolonged rest in bed. The mechanical effect alone is of course considerable, but the functional rest which it gives to the reflex centres of the spinal cord, by the mere cessation of bodily movements, is equally important.

Mechanical appliances for the fixation of the spinal column are more useful in irritations of the bones and muscles than of the cord itself. Yet it is often the case that all these structures are more or less strained and injured, so that what helps the recovery of one helps all. For sprains of the back, with or without definite injury of the cord, casts and splints are decidedly useful. By immobilizing the spinal column they aid materially in securing perfect rest to the injured cord and membranes, and so hasten their recovery.

Sedatives should be used cautiously, and not too continuously, where there is reason to suspect that a general condition of depression already exists. Bromides in moderation are allowable, particularly to induce sleep, the loss of which is of itself extremely depressing; but Page warns us against the prolonged exhibition of the bromides, on account of their depressing effects.

WOUNDS OF THE SPINAL CORD.—The results of wounds of the cord and membranes depend largely upon the failure or success of closure by first intention, the absence or presence of suppuration, or, in other words, of septic infection.

Of the more favorable type a case has already been mentioned.

Hurd (1845) described an instructive case of a man who fell upon his back in jumping from a wagon.

"In attempting to rise he found his lower extremities paralyzed; calling for help, he stated that a chisel, which he had carried in his coat-tail pocket, was sticking in his back; to extract it required the united efforts of several men. It measured five inches in length to the shoulders, was seven-eighths of an inch in width, and one-eighth of an inch in thickness at the cutting end. It had entered to the shoulders. During the extraction the patient suffered very little, but said he saw, apparently, vivid flashes of light, which were followed by total darkness. The wound was opposite the lower dorsal vertebræ. There was total loss of cutaneous sensibility below the wound, with the total loss of voluntary motion, and paralysis of the bladder and rectum.

"The patient was prostrated for forty hours, and then reaction was followed by fever for several days. The wound healed rapidly. The urine was withdrawn by the catheter for eight days. Cutaneous sensibility returned on the fifth day, and imperfect use of the limbs about the fifteenth. After five years he still walked with crutches."

This case, which is not entirely exceptional, is an illustration of the favorable results which follow primary union and the avoidance of suppuration. While there is a lack of absolute proof that the cord was even partially severed, there is a strong probability, almost amounting to a certainty, that this was the case.

The results of laying open the spinal canal, where septic infection occurs, are in startling contrast to the above.

Acute purulent inflammation of the cord and membranes, well deserving the name *foudroyant* which has been applied to it, soon terminates the life of the patient.

Chills, followed by pyrexia and general hyperæsthesia, with paralysis below the point of injury, usher in the attack. Tetanic spasms of the muscles occur, as in cases of cerebro-spinal meningitis. Delirium, coma, and death very shortly follow. Post-mortem examination reveals extensive inflammation of the meninges over the whole cord and base of the brain.

Gunshot wounds of the spinal cord are not essentially different from wounds received in other ways. They are seldom uncomplicated by wounds or fractures of the vertebræ.

The treatment of wounds of the cord should be conservative, so far as circumstances allow; *i.e.*, the wound should be as little explored and disturbed as possible, save for disinfection in certain cases.

Primary closure should be sought by every means possible. It is not to be forgotten that bullet wounds are often favorably inclined toward healing even when the bullet is not extracted, and that, rather than disturb the newly formed coagula which seal such a wound, it is safer, in some locations, to leave the bullet. It is generally safe to do this, since, from their form and unirritating properties, leaden bullets are now known to be among the least objectionable of foreign bodies. The general principles of the treatment of wounds of the cord are the same as those to be followed in cases of simple injury. *Edmund Andrews.*

SPINAL CORD DISEASES: LATERAL SCLEROSIS.

(*a*) PRIMARY LATERAL SCLEROSIS.—Synonyms: Spastic spinal paralysis; tabes dorsal spasmodique.

Definition.—The disease is characterized by a gradually progressing paralysis, which begins in the lower extremities, is accompanied by greatly exaggerated tendon reflexes, muscular rigidity and contractures, and is not attended by sensory, trophic, or visceral symptoms. The anatomical basis is supposed to be a primary sclerosis of the antero-lateral columns.

Etiology.—We know very little of the causes of the disease. It occurs chiefly in adults, more frequently in men than in women. Exposure, excessive venery, etc., have been assigned as causes in individual cases. Some cases occurring near Rome, several of which were in one family, seemed to be due to the effects of a leguminous article of diet, *lathyrus cicera*.

Symptoms.—The disease begins with weakness in one or both lower extremities. There is an undue sense of fatigue on exertion, and an objective examination shows a slight paresis. There is at the same time some difficulty in walking, this being, at first, most noticeable on rising in the morning. As the paresis increases, motor irritation symptoms are soon manifested. These are at first slight clonic or tonic spasms of the affected muscles. They are most likely to occur when the patient is fatigued, are easily evoked by active or passive movements of the limbs, but often come on in the middle of the night. The tendency to muscular spasm—brought on by either a voluntary or a passive movement, or in a reflex way—increases to such an extent that complete muscular rigidity and contractures of the limbs occur. This condition antagonizes every action of the patient, makes his voluntary efforts altogether futile, and, therefore, causes the paralysis to appear more complete than it really is. The rigidity can usually be overcome, in early periods, by slow persistent pressure, but when it becomes excessive it resists powerful efforts. The usual position of the rigidly contracted limbs is that of extension at the knees, the feet in the equino-varus position, and the thighs firmly pressing against one another. Their immobility is often interrupted by clonic spasms, and occasionally the limb is drawn for a short time into another position.

A striking, and usually an early, symptom is the exaggeration of the deep reflexes. The patellar tendon reflex is greatly exaggerated; muscular contractions can be elicited by striking any of the tendons—the inner or outer hamstrings, etc., where tendon reflexes cannot be elicited, as a rule, in health—and even tapping over the periosteum will produce like manifestations. But the most striking of these phenomena is the ankle clonus, rapid and rhythmical clonic contractions taking place when the foot is sharply flexed, and continuing as long as the foot is held in a flexed position. When the reflexes are much exaggerated the clonic contractions, on evoking the ankle clonus, may not be limited to the ankle, but may extend to all the muscles of the extremity. The ankle clonus also becomes a disturbing element in walking, as every time the body rests on the toes in progressing forward there is a tendency to its production.

The gait is very characteristic. As the legs are weak and stiff the feet cannot be freely lifted, and, when moving forward, sweep the floor, making an almost characteristic scraping sound. At the same time, in order that the foot can be brought forward, it makes a wide out-

ward sweep. The gait is sometimes further impaired by clonic spasms of the muscles—those representing the foot clonus, as just described—which may cause a temporary halt in walking, or may make that act altogether impossible. Walking is more difficult on an up or down grade, and on an uneven surface, than on the level and on an even surface. It usually becomes easier after the patient has walked for a while.

The disease slowly extends upward, involving the muscles of the abdomen, back, and upper extremities. The latter are usually affected to a less degree than the lower extremities, though exaggerated reflexes and muscular tension are associated with the paresis. They may even be rigidly contracted. In that case the position is usually one of slight flexion and pronation of the forearm, and strong flexion of the wrists and fingers, the arm being pressed firmly against the body.

In typical cases there are no further symptoms on the part of the nervous system. The sensibility is intact, the functions of the bladder and rectum normal, there are no trophic changes in muscles or skin, and no special changes in the electrical reactions.

The symptoms do not always appear in the order just given. In rare instances the disease attacks the upper extremities before the lower, or occurs first in hemiplegic form, the arm being affected on the same side as the leg before the second lower extremity is involved. The progress of the disease is usually very slow. Though the patient be altogether bedridden, and without power of motion, the general health need not suffer. Unless there be some complication he may live to old age.

Morbid Anatomy and Physiology.—Symptoms like those of spastic paralysis had been observed with various diseases, but Erb was the first to describe this as a separate and distinct disease, whose basis he believed to be a primary sclerosis of the antero-lateral columns, especially the pyramidal tracts. His views have been pretty generally accepted, but yet, it must be acknowledged, there has not been much positive evidence to substantiate them. In a number of post-mortem examinations, where this disease was diagnosed during life, lesions in the brain, tumors in the medulla oblongata, diffused scleroses, etc., were found. In only a few instances did the disease appear to be a primary sclerosis of the lateral columns. But it is probable, whether or not a primary disease be usually found, that the pathological changes in the lateral columns produce the symptoms of this disease, for when spastic symptoms are found with multiple sclerosis, diffuse myelitis, etc., the lateral columns are found to be affected.

The paresis or paralysis is explained by the destruction of nerve-fibres in the pyramidal tracts, the tracts conveying voluntary motor impulses. The motor irritation symptoms cannot be so satisfactorily explained. Charcot believes them to be due to dynamic changes in the large ganglion cells, these being placed in a state of irritation by the degenerated nerve-fibres of the pyramidal tracts, which terminate in them. Hughlings Jackson supposes that the influence of inhibiting centres in the brain is removed by the destruction of the pyramidal tracts, and thence arise the excessive motor manifestations.

Diagnosis.—The symptoms of spastic paralysis may appear with multiple sclerosis, transverse or diffuse myelitis, or brain lesions. In these cases we must look for the further symptoms of these various diseases, indications of involvement of the gray matter and posterior columns in transverse myelitis, optic atrophy, nystagmus, intention tremor in multiple sclerosis, etc. In cases of multiple sclerosis there may for a long time be no other symptoms than those of spastic paralysis, in which case a correct diagnosis would be impossible.

Quite a number of cases have been reported in which there was apparently primary sclerosis in various strands of the spinal cord, termed combined systematic disease. In these, symptoms like those of lateral sclerosis were often found, but there were usually additional manifestations, symptoms on the part of the bladder, etc.

Yet it is quite probable that, in case of primary disease in the lateral columns, there might, with the lapse of time, be extension by contiguity of surface, and thereby the number of symptoms as well as the extent of disease be increased.

At present we can only make a diagnosis of spastic spinal paralysis. We cannot be certain, during life, that the disease in the lateral columns is primary, nor that it is altogether limited to that part of the cord.

Prognosis.—When uncomplicated the disease does not appear to shorten life. It is sometimes capable of improvement, and even cures have been reported.

Treatment.—The treatment applicable in these cases is that usually adopted in locomotor ataxia and other forms of chronic myelitis. Rest in bed for a number of weeks, especially when there seems to be an exacerbation of the disease, may produce amelioration of the symptoms. Hydrotherapy in its various forms, sponge-baths, wet packing, cold, and in some instances hot, baths, deserves trial. Electricity is the therapeutic agent in most common use, and, perhaps, of greatest power. Both the galvanic and faradic currents may be tried, and applied to the paralyzed muscles as well as over the spine. Probably most can be hoped from the central application of the constant current.

Various drugs have been administered. Probably the greatest reliance has been placed upon nitrate of silver, and, especially when there has been an antecedent syphilitic history, iodide of potash.

(*b*) Amyotrophic Lateral Sclerosis.—For both the description of the symptoms and knowledge of the anatomical character of this disease, we are chiefly indebted to Charcot. Though somewhat akin to the disease just described, it presents striking differences both in its symptomatology and morbid anatomy. It occurs chiefly in persons of middle age, but has been observed in children.

Symptoms.—The disease usually begins with paralysis of the upper extremities, which is soon accompanied by atrophy and fibrillary contractions of the paralyzed muscles. Subsequently muscular rigidity and contractures occur, the arms assuming the position found in spastic paralysis, partly flexed at the elbows and pressed against the body, forearms pronated, hands and fingers strongly flexed. These contractures may remain even when the muscles are almost completely atrophied. Usually, after the lapse of a number of months the lower extremities become involved. In them the manifestations are mostly like those of spastic paralysis—paralysis, exaggerated tendon reflexes, muscular rigidity, contractures—while little or no atrophy of the muscles is observed. The electrical reactions are altered according to the degree of muscular atrophy. In the lower extremities there may be a mere quantitative change, diminution of electrical irritability, while in the upper extremities the alteration is usually more marked, and, when the muscular atrophy is rapid, as often occurs in the small muscles of the hand, typical reaction of degeneration may be found.

At a still later period bulbar symptoms, those of glosso-labio-laryngeal paralysis—atrophy of the lips and tongue, difficulty in deglutition, indistinct speech, respiratory disturbances—appear, and finally carry off the patient.

The symptoms do not always appear in the order described. Sometimes the disease begins in the lower extremities, extending thence to the upper, and finally to the cranial nerves. Sometimes the disease begins as a bulbar paralysis, though it need not, therefore, run a rapid course.

The degree to which spastic symptoms, and to which muscular atrophy appear in both upper and lower extremities is also quite variable, depending upon the part of the nervous system in which the morbid changes began, and upon the extent to which the gray and white nervous tissues are respectively affected.

The duration of the disease is usually from one to three years. The well-marked cases hitherto recorded terminated fatally. Death is generally caused by the bulbar symptoms.

Morbid Anatomy and Physiology.—The morbid changes are almost, if not altogether, limited to the motor central and peripheral nervous apparatus. There is sclerosis—

atrophy of the nerve-fibres and increase of the connective tissue—of the direct and crossed pyramidal tracts in the cord, often extending above the crossing of the pyramids in the medulla, and in two cases of Charcot and one of Koshewnikow, the morbid changes could be followed to the cortical motor area in the upper half of the central convolution. There is atrophy of the large ganglion cells of the anterior cornua, and of the cells of the nuclei of the affected cranial nerves. Certain of the cranial nerves, of the anterior roots of the spinal nerves, of the mixed nerves, and of the muscles, are also found in various stages of atrophy.

As to the explanation of the symptoms, the muscular atrophy is due to the atrophy of the large ganglion cells, the bulbar symptoms to disease of the nuclei of the cranial nerves, the spastic phenomena to sclerosis of the pyramidal tracts. The preponderance of spastic or atrophic manifestations is due to preponderance of the morbid process in the white or gray matter, respectively.

Diagnosis.—The diagnosis must be based on the order of appearance of the symptoms, but chiefly upon the combination of spastic and atrophic phenomena. An early diagnosis is often impossible—for instance, to distinguish the disease, when it begins with bulbar symptoms, from ordinary glosso-labio-laryngeal paralysis. But some pathologists have considered these and some other chronic affections as really the same process, only in varying degrees of development.

The prognosis is sufficiently indicated in the foregoing description. Such treatment may be resorted to as is employed in other chronic diseases of the cord.

Philip Zenner.

SPINAL CORD DISEASES: MENINGEAL HÆMORRHAGE. Definition.—Spinal Meningeal Hæmorrhage, Hæmatorrhachis, Spinal Meningeal Apoplexy, is a hæmorrhage into the spinal canal in, between, or about the membranes of the spinal cord. As an uncomplicated affection it is of rare occurrence, but in cases of traumatism it is often associated with injuries of the cord itself.

Varieties.—The hæmorrhage in spinal meningeal apoplexy may be either extra-dural, *i.e.*, outside of the dura mater, in the loose connective tissue between that membrane and the bony walls of the canal, or sub-dural. In the latter, the hæmorrhage may be inter-arachnoideal, between the layers of the arachnoid, as formerly believed, or sub-arachnoideal, in the connective tissue between the arachnoid and pia mater, on the surface, or in the meshes of the pia mater, or on the surface of the cord itself.

Pathological Anatomy.—In extra-dural hæmorrhage the blood is effused on the outer surface of the dura mater and in the loose connective tissue outside of that membrane. The effused blood, unless excessive in amount, is, as a rule, coagulated, and limited in longitudinal extent to the length of two or three vertebræ; it may surround the whole cord in the form of a ring, or be located on the anterior or posterior surface of the organ, more often the latter; it follows, as a rule, the nerve-roots arising from the affected region.

The dura mater and tissues around are stained, ecchymosed, and covered with clotted blood, to a greater or less depth. When there has been any compression of the cord or of the nerve-roots, these are found red and softened at the injured spot, and bloodless beyond. The spinal fluid is dark and turbid. The bloody effusion is more often limited to one spot, but it may occur in several places, and it may be so profuse as to fill up the whole spinal canal. This form of meningeal hæmorrhage is the most common, comprising about three-fourths of the reported cases.

In sub-dural hæmorrhage, the inter-arachnoideal of some authors, the blood is generally fluid, sometimes, however, coagulated, and lies loosely between the dura mater and arachnoid. In this form, which is rare, the source of the hæmorrhage is cranial or from rupture of spinal vessels. Hæmatoma of the spinal dura mater, pachymeningitis hæmorrhagica, is, of course, not included. Pigmentation and ecchymoses of the meninges, with secondary inflammation, form the only pathological changes to be observed.

In the sub-arachnoideal form the blood is diffused and coagulated beneath the arachnoid, in the loose connective tissue, or between the meshes of the pia mater and on the surface of the cord; encircling, either totally or partially, that organ. In longitudinal extent, the effused blood is limited generally to the length of two or three vertebræ, and it may be found at two or more places. The membranes are stained and ecchymotic, and the cord is reddened at the affected spot, but there is little, if any, compression; the spinal fluid is colored.

The inflammatory signs following spinal meningeal hæmorrhage are very limited, and consist in thickenings, adhesions, and pigmentation of the membranes.

Etiology.—The causes of simple uncomplicated hæmorrhage into the spinal meninges are not very well known. The peculiarity of the circulation in the spinal canal, in which a number of small vessels anastomose very freely, and so diminish the tension of the blood-column and equalize the pressure, does not favor its occurrence; and again, the degeneration of the coats of the vessels, which we see playing such an important part as a factor in cerebral hæmorrhage, does not seem here to obtain so easily and is never so pronounced. Age does not seem to predispose in any way to it, and though the greater number of cases are found among men, this does not appear to be due to any particular susceptibility, but rather to the greater exposure to traumatism of that sex.

Among the exciting causes traumatism is by far the most frequent; to be brief, fractures and dislocations of the vertebral column, blows, and falls on the buttocks or feet causing concussion of the column, deserve to be specially mentioned. Syphilitic caries of the vertebræ, and the rupture of thoracic or abdominal aneurisms into the spinal canal, have been shown to have caused the affection in some cases. The rupture of spinal vessels, either from degeneration of their coats or from other causes, and the gravitation of the blood in cranial hæmorrhages, have been regarded as etiological factors in several cases. The sudden cessation of the menstrual flow, or hæmorrhoidal flux, violent bodily exercise, and the rupture of vessels in eclampsia, tetanus, and other spasmodic diseases, are believed in certain cases to be able to produce the affection. Finally, post-mortem examinations have shown that spinal meningeal apoplexy does occasionally occur in the course of long and protracted diseases, such as scurvy, purpura, typhus and typhoid fever, pyæmia, yellow fever, hæmorrhagic malarial fever, etc.

Symptoms and Clinical History.—The symptoms caused by hæmorrhage into the spinal meninges will vary according to the locality affected, and the amount of the hæmorrhage. The onset is, as a rule, sudden, though in exceptional cases it may be preceded for a day or two by feelings of languor, stiffness of the back and neck, and other indefinite symptoms. The most prominent symptoms are a sudden tearing pain in the back, at the site of the lesion, followed or accompanied by various symptoms denoting irritation, both of the motor and sensory nerve-roots, and of the spinal meninges. These are stiffness of the back, neck, and limbs, increased upon motion; jerking, spasmodic contraction of the muscles, neuralgic pains, numbness, formication, and hyperæsthesia of the parts. These irritative symptoms are soon followed by others of paralysis and anæsthesia, but these are, as a rule, never complete. The bladder and rectum are little, if at all, affected; the mind is clear except in cases in which the shock is very great. The inflammatory reaction which follows is generally of short duration, seldom lasting more than a day or two, and the fever and general symptoms are, on the whole, mild.

The symptoms are more or less modified, according to the segment of the cord affected. When the hæmorrhage occupies the cervical region, the pain and stiffness, together with the hyperæsthesia, are more marked, and sometimes altogether confined to the upper extremities and neck; the breathing may, or may not, be disturbed,

according as the root of the phrenic nerve is implicated or not; interference with the cilio-spinal centre will cause flushing of the face and neck, and dilatation of the pupils, followed by paleness of the parts and contraction of the irides.

When the lesion is situated in the dorsal region, the stiffness and pain are limited to that region of the back and a distinct girdle sensation is complained of; the patellar and other reflexes in the lower extremities are increased.

When the lumbar portion is affected, the symptoms are referred to the buttocks, perineum, and genitals, and the bladder and rectum are, as a rule, partially paralyzed. The tendency of the affection is toward recovery, but that may sometimes be protracted. Death is not rare in excessive hæmorrhages or in complicated cases.

The following case is selected from several in my note-book, and serves to illustrate clearly the affection.

H. B——, aged thirty-three, a car-driver by occupation, drinks and smokes moderately, has never had syphilis, gives no family history of disease, has been subject to bleeding piles for years. About July 1, 1886, he had an attack of diarrhœa, followed by costiveness, and from that time the bleeding from the hæmorrhoids ceased. On July 3, about 9 P.M., he was sitting on his car, wet with perspiration, exposed to a rather cool breeze, when he felt a sudden tearing pain in the back, in the upper lumbar region; he tried to get up, but his legs became stiff and shaky, and he could not move them; the affected parts were numb; he could not bear to have them touched, and he felt as if ants were creeping up his feet. In this condition he was taken home on a stretcher, the least motion of his back increasing the cramps and spasms in his legs, and giving rise to shooting pains. On the next day he had slight fever, and his other symptoms grew worse; he could not move the legs at all, and could not bear to have them touched; there was retention of urine, with dribbling; the bowels were costive.

The patient was admitted in the ward for nervous diseases of Charity Hospital on July 7, 1886, when the following notes of the case were made: General appearance good; pulse, 108; temperature, 99½° F.; respiration, 22. He complains of great pain, increased upon pressure and motion, over the lower dorsal and first lumbar vertebræ, and of a girdle-feeling around the abdomen at about the level of the anterior-superior iliac spine; the lower extremities are well nourished, but almost completely paralyzed; the muscles are flaccid, the bladder is unable to retain urine for any length of time, but the patient has time to call for assistance, and so keeps from wetting his bed; the bowels are costive; sensation, both general and tactile, in the affected part is very much lessened, and feelings of formication and numbness still persist. The patellar tendon reflexes are greatly diminished, scarcely perceptible. The mind is clear, and the upper extremities are normal. He was put on a mixture of five grains of iodide of potassium and thirty drops of the fluid extract of ergot every three hours; small doses of morphine, with large doses of bromide of potassium, were given two or three times during the night to relieve the pain in the back and the crampy feelings which, he said, were always worse at that time; counter-irritation by means of tincture of iodine was made along the vertebral column every other day.

On August 29th the pain in the back and the muscular spasms had greatly subsided; the patient could lie on his back and permitted himself to be moved; he had some power in the lower extremities, but could not lift his feet from the bed; the anæsthesia still persisted, though somewhat ameliorated; the formication and numbness were lessened; the bladder and rectum were normal. Electrical examination made at this time showed lessened galvanic and faradic irritability. Counter-irritation was then stopped and mild galvanic currents to the spine were begun, and the faradic current was applied to the affected extremities. Iodide of potassium was continued in ten-grain doses three times a day. In the latter part of September the patient was able to stand on his legs, the feeling in those parts slowly returning; formication had disappeared, and, aside from a slight numbness, the parts felt well.

From that time the patient slowly improved until December 18, 1886, when he was discharged as cured.

DIAGNOSIS.—The suddenness of the attack, the acuteness of the pain, the symptoms of irritation first, soon followed by mild symptoms of paralysis, the moderation of general symptoms and the rapid subsidence of the same, and the tendency to improvement and recovery, make simple uncomplicated cases of spinal meningeal hæmorrhage in most instances easy of diagnosis. The affections with which it is most likely to be confounded are the following: Spinal meningeal congestion, medullary hæmorrhage, spinal meningitis, myelitis, and simple concussion. In hyperæmia of the spinal meninges the symptoms come on gradually and are not constant, remissions occurring at different periods of the twenty-four hours.

In medullary hæmorrhage (spinal apoplexy) the symptoms of paralysis and anæsthesia are sudden and complete, and the tendency to spasms is altogether absent. Death is rapid, or incurable paralysis is the result.

Meningitis and myelitis can generally be recognized by their slower evolution, by the high fever, and by the general symptoms.

In simple concussion spasm is generally wanting, and the symptoms of paralysis come on early.

PROGNOSIS.—The prognosis depends on the amount of hæmorrhage and on the seat of the lesion. When the hæmorrhage is small, the causal injury slight, the inflammatory and reactive symptoms mild, the paralysis not too extensive and profound, and the patient young, the prognosis, as a rule, is favorable. But when, on the contrary, the shock is great and the hæmorrhage profuse, when the cervical region is implicated, the paralysis profound, and the fever and general symptoms severe, the prognosis is correspondingly bad. The affection, however, lasts for several months, even in the most favorable cases.

TREATMENT.—The treatment should at first be directed to the limiting of the hæmorrhage and the diminution of the reactive symptoms. For the first purpose, absolute rest in bed, on the side or on the abdomen, the internal and hypodermic administration of ergot in half-drachm or drachm doses every hour or two, or of ergotine in large doses, tincture of belladonna to the full physiological limit, cold applications to the back by means of ice-bags or otherwise, the local abstraction of blood by means of cupping, leeches to the back of the ear or to the anus, and, in plethoric subjects venesection, hot applications to the extremities, and repeated drastic purges, are to be recommended. To meet the second indication, cooling drinks and mild antipyretics are of service. Later on, the reabsorption of the effused blood should be facilitated, and the anæsthesia and paralysis properly treated by means of counter-irritation to the spine by iodine, blistering, or dry cupping; by the internal administration of the iodide of potassium in large doses, massage, passive exercise, the use of electricity, both galvanic and faradic, and the administration of small doses of mercury and general tonics.

If pain be present, narcotics are naturally indicated; to relieve spasms, the bromides and chloral hydrate are of great value.

Much can be done to prevent the affection by proper treatment of suspended menstrual and hæmorrhoidal discharges, and by relieving hyperæmia of the cord.

SPINAL CORD DISEASES: MULTIPLE (CEREBRO-SPINAL) SCLEROSIS. Synonyms: Disseminated sclerosis; insular sclerosis.

DEFINITION.—This disease may present manifold symptoms, the most common of which are paresis, with muscular rigidity and exaggerated tendon reflexes as in spastic paralysis, tremor brought on by voluntary movements, nystagmus, scanning speech, amblyopia, apoplectiform attacks, and impaired intellect. The anatomical basis of the disease consists of disseminated patches of sclerosed tissue in various parts of the central and peripheral nervous systems.

ETIOLOGY.—An hereditary influence has been traced in a few instances. Charcot states that the disease occurs most frequently in females, but a number of other observers do not concur with him in this view. It occurs most frequently between the ages of fifteen and thirty; occasionally in young children; rarely, if at all, after forty.

Traumatic influences, such as blows on the head, concussion of the whole body, exposure, hardship, overwork, and profound emotional disturbance, may all be mentioned as occasional exciting causes. In a number of instances the disease developed after the existence of an acute disease, typhoid fever, variola, etc.

SYMPTOMS.—The areas of diseased tissue may involve any part of the nervous system and may occur in any number, while the disease may be of various degrees of severity; and the symptoms, which are but the expression of the locality and intensity of the disease, may make the most varied clinical pictures. There may be an entire absence of symptoms of disease of the nervous system, though sclerosed nodules are found post mortem; or the disease may simulate various different organic or functional nervous diseases. But, nevertheless, the sclerosis seems to have a predilection for certain parts of the nervous system, and we find, accordingly, in many cases similar, and almost characteristic, clinical appearances.

A cerebral and a spinal form of multiple sclerosis are sometimes spoken of, but usually both brain and cord become involved in the disease, though it may have been present in the one some time before it was in the other. Generally the spinal cord is first affected.

The disease usually begins very insidiously and is slow in its progress; in rare instances it has an abrupt beginning, perhaps is ushered in by an apoplectiform attack. The earliest symptoms may be of cerebral origin, such as headache, vertigo, ataxic gait, and slight psychic disturbances; or there may be a slight tremor in one or both hands; but more frequently the symptoms are those of spastic paralysis.

At first there is weakness of one leg, then of both, attended by some difficulty in walking. Gradually, with increasing paresis of the limbs, there appear muscular rigidity, especially brought on by active or passive movements, exaggerated tendon reflexes, spastic gait, and, finally, rigid contractures of the limbs. The paresis, and, to a less extent, muscular rigidity, etc., at a later period affect the upper extremities, and to these is subsequently added another motor symptom—one of the most prominent and characteristic of this disease—the so-called intention tremor, tremor during the performance of a voluntary act. Before it is otherwise noticeable, it may be observed in the handwriting or other delicate movements of the fingers, especially if the act is slowly performed. The writing, if carefully observed, will be seen to be full of small indentations which occur with great regularity, indicating that the tremor is rhythmical. When the tremor is well marked any voluntary movement will cause it to appear, and it may be seen to some extent during rest. A common method of eliciting the symptom is to ask the patient to put a glass of water to his lips. The tremor increases and the oscillations of the hand are greater as the latter approaches the mouth. The trembling may become so violent that the water is thrown out of the glass and the effort proves futile. When the patient is sitting quietly either there is no tremor, or slight movements of the head and trunk may be observed. If he now perform a voluntary act, as lifting an arm, the tremor in the head and trunk increases at the same time that there is tremor of the acting member. When he attempts to walk there may be such violent tremor of the limbs and trunk as to make walking, or even standing, almost impossible. On the other hand, when the patient lies down and every part is well supported no tremor appears. None is observed during sleep. It is increased by emotional excitement.

All the voluntary muscles may be thus affected, the head as well as the trunk and limbs. Tremor in the face is less commonly seen, though there may be irregular movements, choreic in character.

The distinctive features of the tremor are that it is rhythmical, and that it occurs only with muscular efforts. A very few cases have been reported where it continued even in rest, but such cases are exceedingly rare. The tremor is not found in all cases. It probably depends on the locality of the disease. It also disappears in any part when the latter has become completely paralyzed.

The tremor can usually be easily distinguished from that of other diseases. In paralysis agitans, in the beginning (and it is only then that the two diseases could easily be confounded), only a few fingers are affected, and the oscillations are fine and very rapid. At the same time the tremor has somewhat the character of co-ordinated movements. Thus the movement of the thumb upon the fingers has been likened to that of counting money, rolling pills, etc. The tremor of multiple sclerosis is large and coarse, with no appearance of co-ordinated action. In paralysis agitans, furthermore, the tremor is, to some extent, controlled by voluntary movement, and increases with rest, and the head is very rarely affected. When the tremor is violent it may have the appearance of the movements of chorea. But the latter occur during repose as well as during volitional acts, and they cause an intended movement to be made very irregularly; on the other hand, in multiple sclerosis the general direction of any movement is maintained, but the line of movement is an undulating one, the undulations playing equally up and down along the central line of direction.

The next two symptoms seem to be similar in character to the tremor. The first is nystagmus, a very common symptom, and of value in diagnosis. When not otherwise noticeable, it may be made manifest by movements of the eyes, strong convergence, or forced movements in some direction. The other symptom is scanning speech. Other changes of speech are sometimes present, but this is the most common and most characteristic, and, therefore, of high diagnostic value. The speech is slow and dragging, each syllable being pronounced separately as in the slow scanning of verse, and, therefore, termed scanning speech. If the patient attempts to speak more rapidly, his words are likely to be so jumbled together as not to be at all understood. The voice is monotonous to the highest degree. There is often tremor of the lips at the same time, and, on laryngoscopic examination, there has been found to be diminished tension of the vocal cords.

Other ocular symptoms besides nystagmus are frequently found. Double vision, due to paralysis of some of the external muscles of the eye, occurs, just as in locomotor ataxia, either as a transient symptom at an early period of the disease, or as a permanent condition at a later stage. Amblyopia is also a common symptom. Generally there is only impaired vision, not complete blindness. The ophthalmoscope reveals, in these cases, a discoloration of the disks, due to a degree of atrophy of the optic nerves.

Headache and vertigo are often present, both in the early and in the later stages of the disease. The vertigo often occurs in paroxysms. Occasionally it is due to the double vision, but more frequently it is quite independent of the latter condition.

The mental symptoms often play an important rôle. Slight psychic symptoms may be manifested in the beginning of the disease if the latter first affects the brain, but the graver symptoms are, usually, late manifestations

Change in disposition, irritability, loss of self-control, a tendency to laughing and crying, are common conditions. A certain impairment of intellect—weakened memory, a degree of apathy, etc.—is, also, not uncommon. But a high degree of dementia is rare. It is only likely to occur when the disease begins at an early age and there is arrested development of the brain, or when the pathological process is very acute. Different forms of insanity are sometimes observed, most frequently melancholia, occasionally delusional insanity.

Apoplectiform seizures, like those seen in general paralysis, are important symptoms. They occur, according to Charcot, in one-fifth of all cases. After slight prodromal symptoms, headaches, etc., coma develops within a few hours, the temperature rapidly rises, often reaching 104° or 105° F., and at the same time the face is flushed and the pulse rapid. Hemiplegia, with flaccidity of the paralyzed muscles, is soon observed. Within a day or two consciousness returns, the temperature falls, and, within a comparatively brief period, the paralysis disappears. Such attacks may occur every few months, or very rarely. They usually leave the patient in a permanently worse condition, thus marking the progress of the disease. Sometimes the patient dies in the attack. These seizures are very much like those of apoplexy, but post-mortem examinations reveal no anatomical basis for them.

In the foregoing have been given the most common symptoms of multiple sclerosis, those found in the majority of cases. But, on account of the distribution of the diseased areas, various other symptoms may be manifested. Thus the disease may attack the posterior columns of the cord, and ataxia, pain, anæsthesia, paræsthesia, etc., will be present; or it may involve the gray matter, when atrophy and paralysis of muscles will ensue. Or the disease may involve the whole thickness of the cord and produce the symptoms of transverse myelitis. When the posterior as well as the antero-lateral columns are affected, many of the appearances of spastic paralysis are likely to be absent, especially the exaggerated tendon reflexes. Symptoms referable to the bladder, rectal, and genital functions are also likely to appear. If the disease involve the nuclei of the facial, hypoglossal, and pneumogastric nerves, the ordinary symptoms of labio-glosso-laryngeal paralysis will be manifested, and various local cerebral symptoms may appear, according to the location of the foci of disease.

The course of the disease is a very chronic one. Charcot has divided it into three stages—a division applicable to those cases which present the common clinical picture.

The first stage is from the beginning of the disease to the period of complete disability from paralysis and contractures of the limbs. This stage may last from two to six years or longer. The symptoms are very slow in their progress. They begin as spinal or cerebral, but both sets of symptoms appear before this stage is terminated. There is often an arrest of the symptoms, or even improvement, which indefinitely prolongs this stage, and may give rise to delusive hopes of complete restoration to health.

The second stage, that of the fully developed disease, may last also from two to six years. There seems to be little change in the patient during this period, and, though entirely helpless, he seems not to suffer in general health.

The third stage is that of decline. The general health is affected, there is loss of appetite, wasting, etc. Cystitis, decubitus, pyæmia, etc., may hasten the end. Or the latter may be due to an increase in the bulbar symptoms, or to an apoplectiform attack. More frequently a fatal termination is caused by an intercurrent affection—pneumonia, typhoid fever, or, above all, phthisis.

The average length of the disease is from six to eight years. In rare cases it terminates in a year or two. Occasionally it lasts twenty years.

Morbid Anatomy.—The pathological changes can usually be seen by the naked eye. They consist of numerous patches or nodules of sclerosed tissue scattered throughout the nervous system. The nodules vary in size from merely microscopical proportions to that of a chestnut or larger, are rounded or irregular in shape, and may often be seen on the surface as slight prominences or depressions, but are found in larger number on making sections of the brain and cord. Their color is mostly of a gray or reddish-gray; they are translucent, and have a firm, often cartilaginous, consistence. Many of the nodules are of the same color as the surrounding tissue, and are only distinguished by their consistency. In rare instances a few may be softer than the normal tissue, probably indicating recent disease; most of the nodules, on the other hand, doubtless being of very old standing, for such cases come to the post-mortem table only after the disease has existed a long time. The nodules seem to be quite distinctly circumscribed, but the microscope reveals that they merge imperceptibly into the healthy tissue. They are also quite distinct, as a rule, though occasionally they blend into one another. In rare instances there has been found a diffuse sclerosis in both the brain and cord, which, to some extent, has united the scattered nodules. On the other hand, secondary degeneration seems rarely, if at all, to develop from the disseminated disease.

The number of nodules found in a single instance may be very small, or may run into hundreds. Their distribution in the cord is very irregular. In some sections they may be found in the anterior, in others in the posterior, columns; in still others in the gray matter, or they may involve all these parts in the same section. Usually a large number of nodules are found in the medulla, pons, and crura cerebri. It is very rare that these parts are found free from disease. In the hemispheres the walls of the ventricles, corpus callosum, and centrum ovale are favored seats of the disease. In the latter two localities the nodules are often quite large. Usually nodules are also found in the large ganglia, while the cortex generally escapes. But few nodules are, as a rule, found in the cerebellum, and those in the central white matter. Similar nodules may be found in the nerves, most frequently in the optic nerves, but occasionally in the hypoglossal, the nerves of the eye, and the roots of the spinal nerves.

The microscopical appearances are those of interstitial myelitis. The nodules are mostly new connective tissue composed of very fine wavy fibrillæ. But in this new tissue the axis-cylinders of the nerve-fibres can usually be found in large numbers, though their medullary sheaths have disappeared. This is especially true of the nodules in the spinal cord.

At the last meeting of the Society of German Naturalists and Physicians, Adamkiewicz expressed the opinion that the disease is not interstitial, but develops primarily in the nervous tissue, beginning in the medullary sheaths of the nerves. He bases his opinion upon results obtained by a new method of staining the nervous tissue. His view is altogether at variance with that formerly held, and may be looked upon with doubt, at least until further corroboration.

Morbid Physiology.—Many of the symptoms are easily explained by the lesions found: psychic symptoms by disease of the hemispheres, bulbar symptoms by lesions of the medulla, muscular atrophy by lesions in the anterior cornua, anæsthesia and ataxia by disease of the posterior columns, spastic paralysis by disease of the antero-lateral columns—in some instances cerebral lesions may produce the same symptoms—while amblyopia and some other symptoms are often due to nodules in the nerves themselves.

The long retention of the axis-cylinders accounts for the usual presence of paresis rather than paralysis, for the anæsthesia being slight, the amblyopia rarely advancing to complete blindness, etc. (In locomotor ataxia there are also numerous axis-cylinders in the sclerosed area, and the symptoms usually point to only a partial loss of function.) Charcot attributes the tremor to the same condition. He supposes that the axis-cylinders continue to carry voluntary impulses, but, because they are bared of their medullary sheaths, they carry them

Spinal Cord.

in an irregular, jerking manner, and hence the oscillations in the voluntary movements. While this must be considered a mere theory, we can speak with more positiveness of the location of the lesion as a cause of the tremor. It seems to be due to nodules in the medulla and pons, or, at least, in the basilar portions of the brain. In a few cases where the disease was limited to the cord no tremor was observed. On the other hand, when tremor was observed during life, nodules were always found in the medulla and pons; when it was not observed, these parts were not affected to any extent.

With a considerable degree of doubt, we may attribute the nystagmus to lesions in the corpora quadrigemina, the scanning speech to lesions in the medulla, the vertigo to lesions in the medulla or cerebellum. A satisfactory explanation of the apoplectiform attacks has not yet been given.

Diagnosis.—In some instances a diagnosis is made with the greatest ease, in others it is almost impossible. The most common clinical picture—paresis of the extremities with exaggerated tendon reflexes, intention tremor, nystagmus, scanning speech, amblyopia, etc.—is so characteristic that it cannot be mistaken.* But some of the most characteristic symptoms may be wanting, and then the diagnosis is much more difficult. In this case the indications of multiplicity of lesions, and the very chronic course of the malady, must be the guides to diagnosis. When the disease is limited to the spinal cord one can scarcely do more than guess in distinguishing it from other forms of myelitis. In such cases one must be on the lookout for cerebral symptoms. Optic atrophy is often a valuable diagnostic symptom, not only in this instance, but in excluding hysteria or other functional diseases which may simulate multiple sclerosis.

When the sclerosis affects only the brain it may present some of the appearances of brain tumor. Here, too, the indications of a multiple lesion, and the very slow course of the disease, may clear up the diagnosis. But there is another important distinction, in that brain tumors produce to a large extent general symptoms, those of intracranial pressure, such as severe headache, convulsions, and double optic neuritis; while sclerosis produces merely local symptoms, those indicating the loss of function of the part affected by the disease.

The tremor of alcohol, lead, and mercurial poisoning might be mistaken for this disease, but concomitant symptoms and the history of a cause will establish the diagnosis. The tremor of paralysis agitans, with which this disease was formerly confounded, is easily distinguished by the appearance of the tremor, its being controlled to some extent by voluntary effort and increased during rest, and its very rarely affecting the muscles of the head and neck. Furthermore, paralysis agitans is rarely found in persons under forty years of age, while multiple sclerosis rarely occurs after thirty, and, apart from the tremor, the symptoms of the two diseases are quite different.

Prognosis.—Charcot believes that the disease may sometimes be cured, but the opposite view is generally entertained, though its arrest, and even improvement, for a number of years has been observed. It usually runs a very protracted course. When at its inception it manifests itself in various parts of the nervous system at the same time, it is likely to run a more rapid course. The occurrence of apoplectiform seizures, cystitis, bulbar symptoms, etc., hastens the fatal termination.

Treatment.—The same treatment is applicable as in other forms of chronic myelitis, for which see Lateral Sclerosis. *Philip Zenner.*

SPINAL CORD DISEASES: PROGRESSIVE MUSCULAR ATROPHIES. With our increasing knowledge of progressive muscular atrophies the subject is constantly acquiring greater and greater complexity. What was apparently a single, homogeneous condition, has resolved itself, on closer investigation, into a number of apparently distinct affections.

The disease commonly known as progressive muscular atrophy was first described in 1850 by Duchenne and Aran, who regarded it as an independent affection of the muscles. In 1853 Cruveilhier obtained an autopsy on a case of this disease, and was led by what he there found to regard it as the result of atrophy of the anterior roots of the spinal nerves. In 1860 Luys first discovered an atrophic condition of the ganglion cells in the anterior horns of the gray matter of the cord, corresponding to the atrophied nerve-roots, and since that time the myelopathic (spinal) theory of the disease has been the prevailing one. In the past few years, however, the pendulum has swung in the opposite direction, and there is now a strong tendency to the adoption of Friedreich's theory, that all these forms of muscular atrophy are myopathic in origin, and that spinal lesions, when present, are secondary to changes in the muscles.

A comprehensive view of the subject can be obtained by adopting Seppili's classification. He divides progressive muscular atrophies (amyotrophies) into the following classes:

A. *Neuropathic.*—1. Peripheral (toxic, infectious). 2. Central (myelopathics). *a.* Progressive muscular atrophy. *b.* Amyotrophic lateral sclerosis. *c.* Deuteropathic spinal amyotrophies (from extension of disease to the anterior horns).

B. *Myopathic.*—Progressive muscular dystrophy, or progressive primary atrophy. *a.* Infantile progressive muscular atrophy. *b.* Erb's juvenile form of muscular atrophy. *c.* Muscular pseudo-hypertrophy. *d.* Leyden's hereditary muscular atrophy. *e.* Transitional forms.

In the following paper we shall adopt this classification, with slight modifications.

For the sake of convenience we will begin with the consideration of progressive muscular atrophy of spinal origin.

Spinal Progressive Muscular Atrophy. *Etiology.*—This affection, when uncomplicated, occurs in males in the large majority of cases. It is proportionately more frequent in the female sex when it is associated, as so often happens, with bulbar paralysis. Among 16 uncomplicated cases of which the writer has kept notes, all except one occurred in men. Among 214 cases collated by Friedreich and Eulenberg, 167 occurred in males, 47 in females. This great disproportion between the sexes is, perhaps, owing to the fact that males are more exposed to the exciting causes of the disease.

The disease begins most frequently between the ages of thirty and fifty years. Of the writer's 16 cases 3 began before the age of thirty years, 12 between thirty and fifty years, and 1 patient was nearly sixty years of age.

A great many cases have been reported in which heredity seemed to play an important part in the etiology, but the majority of such cases date back to the time when the differentiation between this and other forms of atrophy was not made very carefully. It is very probable that the majority, if not all, of these hereditary cases really belong to the myopathic class of atrophies. Cases seem to be more numerous in families in which there is a neuropathic tendency, but even this has been rarely observed in the cases under my own observation.

Among the exciting causes may be mentioned prolonged exposure to damp and cold, mental depression, syphilis, infectious diseases, and excessive work. Traumatism sometimes appears to determine the occurrence of the disease in the injured part. A few cases have been seen in which it followed a concussion of the spine.

The action of these exciting causes is not very important. They would probably prove inefficient were it not for the existence of some predisposing etiological factor whose nature is entirely obscure, and in many cases they are probably mere coincidences.

Symptomatology.—In the majority of cases the disease begins in the small muscles of one hand. The patient finds that he is gradually growing less able to execute

* Schuler reported a case of tumor of the right hemisphere, in the neighborhood of the island of Reil, which produced the typical clinical picture of multiple sclerosis, and Westphal reported two cases with similar histories, in which no pathological changes were found post mortem. But these are such rare occurrences as not to materially impair the diagnostic value of this clinical picture.

voluntary movements with the fingers, and at the same time the muscles undergo wasting *pari passu* with the loss of power. Then the paralysis and wasting spread to the forearm, usually implicating the flexors and extensors, and, next, the arm or shoulder of the same side. The other arm is then affected in a similar manner, but sometimes the disease appears in both arms almost at the same time. As the disease progresses the atrophy may attack the muscles of the back and lower limbs, the former being less severely affected, as a rule, than the other parts. The muscles of the face remain intact, except in those cases that are complicated with progressive bulbar paralysis. The wasting may be so extreme that the affected limbs finally seem to consist merely of skin and bone. Fibrillary contractions of the muscles are a very constant symptom in the parts affected. A fibre is seen to contract quickly, then the contraction subsides, and again appears in the same or an adjacent fibre. When the disease is widespread these contractions are sometimes visible over a large part of the body. They may be seen in apparently healthy muscles, and then usually indicate the impending affection of these muscles. The mechanical excitability of the muscles is also very often increased.

The atrophied muscles present various electrical reactions. Sometimes there seems to be merely a simple diminution of faradic and galvanic excitability. Careful examination, however, will generally reveal evidences of partial or complete degeneration reaction (usually the former) even at a very early stage of the disease. The attention should be chiefly directed to the rapidity of contraction. On account of the intermingling of healthy and degenerated fibres in the same muscle, the normal contractions of the former may hide the abnormal mode of contraction of the latter, but on making the current sufficiently weak the slowness of contraction is often made evident. AClC is often stronger than CClC.

Cutaneous sensibility remains unaffected during the entire course of the disease. At the most the patients complain of a sense of numbness in various parts, usually the hands, or of a feeling of soreness or slight pain. Trophic disturbances in the skin and deeper parts are rare. The functions of the bladder and rectum remain intact until the end.

The disease advances slowly, with alternate exacerbations and remissions, until the patient is reduced to a condition of absolute helplessness, and dies from exhaustion or from some intercurrent disease. The affection may last from ten to twenty-five years, or even longer.

We will now discuss the symptomatology more in detail.

In a few cases the onset of the disease is preceded by slight aching pain in the parts which are subsequently the first to be attacked, by a feeling of numbness which comes and goes, or by a sensation of coldness. When pain, or other sensory prodromal symptoms are prominent, it is doubtful whether the case should be regarded as one of pure progressive muscular atrophy.

In the majority of cases the disease begins in the small muscles of the hands, usually on the right side. The thenar eminence is the first to be attacked; its normal rotundity disappears and it becomes flattened. At the same time, or a little later, the interossei and hypothenar muscles are involved, the abductor indicis being especially liable to suffer. Unless the patient is obese, depressions then become noticeable in the interosseous spaces. The function of all these muscles is impaired *pari passu* with the wasting. The interossei adduct and abduct the fingers, and, at the same time, flex the first phalanx on the metacarpus, and extend the second and third phalanges. Hence paralysis of these muscles is followed by inability to adduct and abduct the fingers, and leaves the action of the long extensor and flexors of the fingers unopposed. This may result finally in the so-called "main en griffe," the first phalanges being hyperextended, the second and third phalanges strongly flexed. The resemblance to the claw-hand is increased still further when the lumbricales are attacked, as they usually are at a very early period. As a result of the wasting of these muscles the palm of the hand becomes hollowed out. The lumbricales simply aid the interossei in their action of flexion and extension, so that their paralysis increases the extension of the first phalanges, and flexion of the second and third phalanges.

From the hand the atrophy usually spreads to the forearm. In some cases the muscles seem to be attacked quite uniformly, so that the forearm atrophies as a whole. As a general thing, however, the extensors are first involved, the supinator longus usually escaping until the flexors or biceps are attacked, or even until a later period. From the forearm the atrophy extends commonly to the arm, to the biceps and brachialis anticus, while the triceps often remains comparatively intact for a long time. The various movements of the parts are enfeebled, according to the degree of the muscular wasting, but the power of flexion of the forearm on the arm is often retained long after atrophy of the biceps has taken place. The patient then effects this movement by the aid of the supinator longus, which is used as a flexor after the arm has been pronated. In those cases in which the deltoid remains intact the disproportion between the large shoulder and the shrivelled arm is very striking. The deltoid is the next muscle to be affected, though cases are quite common in which this is attacked immediately after, or even before, the hand muscles. Here it is very evident that the muscle is not attacked as a whole, but that certain fibres are picked out here and there by the process, which gradually spreads until finally no muscular tissue may remain. In some cases the atrophy begins in the deltoid, and makes considerable progress in this region before it attacks the small muscles of the hand. With the advancing affection of the deltoid the power of raising the arm from the side is gradually lost; but, even after the muscle is apparently destroyed, the patient is often able to move the arm from the chest, to a certain extent, by throwing the limb out suddenly, with the aid of the pectorals and trapezius, or by sudden movements of the trunk. The normal prominence of the shoulder is lost, the head of the humerus is felt immediately beneath the skin, and the finger can be pressed into the joint cavity. The other arm is usually attacked before the disease has made very much progress in the arm first involved, and the affection runs approximately the same course in both.

From the deltoids the disease spreads commonly to the pectorals, serratus magnus, the scapular muscles, latissimus dorsi, and the rhomboids. As a result of the atrophy of these parts the patient loses the power of rotating the humerus, raising the arm above the horizontal, or drawing the shoulders backward. These muscles are usually attacked at about the same time on the two sides. If the serratus magnus is more markedly atrophied than the other scapular muscles, the attempt to raise the arm beyond the horizontal line will be followed by marked separation of the scapula from the thorax (angel wing), so that sometimes the entire fist may be inserted between the posterior border of the bone and the chest-walls.

The deep muscles of the back and the abdominal muscles, particularly the former, are the next to be involved. The paralysis of the quadratus lumborum and erector spinæ gives rise to a marked lordosis; but whether this condition alone is responsible for the lordosis, as is generally believed, is more than doubtful. In a case at present under my observation, in which there is paralysis of the deep muscles of the back, there is marked lordosis in the erect position, the pelvis being tilted forward at the same time. When the patient sits down, the weight of the trunk thus resting on the tubera ischii, and tilting the pelvis backward, the spinal column is perfectly straight. When this patient bends forward to touch the ground while sitting down, the pelvis is tilted forward and the glutæi muscles are relaxed. On now making the effort to assume the erect position, the pelvis is felt to become vertical and the glutæi muscles at the same time become firm and contracted.

Atrophy of the abdominal muscles is usually not uniform, some parts of the muscles being affected more severely than others. The upper part of the rectus is often

intact, while the lower part of the muscle is very feeble. This condition is first shown by the inability of the patient, while in the recumbent position, to raise the trunk without the aid of the upper extremities. In the erect position there is marked lumbar lordosis, when the erectores spinæ are intact, from the unopposed action of these muscles; but a vertical line from the most prominent part of the spine falls within the sacrum. Vigorous expiration is impeded, and micturition and defecation are also interfered with when the abdominal muscles are wasted. The intercostals seem to be attacked much more often than the abdominal muscles. During inspiration the upper part of the thorax then remains motionless while the lower part is raised. Expiration is interfered with to a greater extent, because the upper two-thirds of the thorax are continually in the expiratory position. This is owing to the fact that the natural tendency of the thorax to undergo narrowing—as the result of the elasticity of the parts—is no longer opposed by the tonic contraction of the intercostals.

Paralysis of the diaphragm is usually a terminal phenomenon. After this occurs full inspiration is attended with sinking in of the epigastrium and hypochondria, and there is very little motion of the abdomen on expiration. The action of the intercostals and auxiliary muscles of respiration becomes exaggerated, unless these muscles are also paralyzed. The patient suffers constantly from dyspnœa, and life is jeopardized by the mildest affection of the respiratory organs.

According to the majority of writers, the muscles of the neck are attacked before those of the lower limbs. This has not occurred as a general thing in my experience. I have usually found that the lower limbs are attacked soon after the upper extremities. The muscles of the anterior leg group, or the extensor quadriceps, are usually involved first. Then the disease spreads to the muscles of the buttocks or calves, lastly to the posterior thigh group. In some cases, indeed, the disease appears first in the lower extremities. Paralysis of the anterior thigh group causes inability to extend the leg, and therefore interferes very materially with walking or rising from a sitting position. In paralysis of the anterior leg group the toes do not clear the ground in walking, and the thigh is therefore flexed more strongly at the hip, producing a very characteristic gait.

Among the muscles of the neck the extensors of the head are usually the first to be involved. As a result of this lesion the head is held back, in order to throw the centre of gravity farther backward, and thus necessitate less muscular action on the part of the extensors. When the head is brought forward it is apt to fall upon the chest, and the patient then experiences difficulty in bringing it back into the vertical position. If the anterior muscles of the neck are also paralyzed, the patient has no control over the movements of the head, and it wobbles from one side to the other with the movements of the trunk.

In advanced stages of the disease the patient is rendered absolutely helpless. He may be entirely unable to move a single part of the body, with the exception of the face and tongue. As a general thing, however, he is carried off by some intercurrent affection before this stage of utter helplessness is reached.

From the very beginning of the disease, fibrillary * contractions of the muscles are an important symptom in the majority of cases, although they are not pathognomonic. In some cases short, fluttering contractions of fibres in different parts of the affected muscles are seen almost constantly, coming on without any apparent cause. In other cases they are not visible, except after irritation of the parts, as, for example, after exposure of the integument to the air, brisk tapping of the muscles with the finger, faradization of the muscles, etc. When the atrophy of the parts is complete the fibrillary contractions cease. The contractions are too feeble to cause movement of the parts into which the muscles are inserted, except in the case of the small muscles of the hand. Here slight movements of the fingers are sometimes produced. The contractions are sometimes observed in parts which are apparently healthy, but they then constitute an indication of approaching disease in the muscle in question. In not a few cases, however, these contractions are unnoticed during the entire course of the ailment.

The mechanical excitability of the parts is sometimes greatly exaggerated, so that a slight tap may produce contraction, not alone of the muscle struck, but also of adjacent muscles. The changes in the electrical excitability of the muscles are very interesting and important from a diagnostic point of view. It has seemed to me that changes are present in all cases. At times the disease may make considerable progress before any other change is noticeable than simple diminution of irritability to both currents, corresponding to the amount of atrophy of the muscles. But in not a few instances we have observed decided changes at the very beginning of the disease. At the present time I have under my observation a case in which the disease has lasted only a few months, and the atrophy is confined to the small muscles of the right hand (thenar and hypothenar eminences, interossei). Nevertheless, the atrophic muscles present a distinct partial "degeneration reaction" (slowness of contraction, excess of An Cl C). It is often very difficult to detect the changes, because the degenerated fibres lie in the midst of healthy ones and the contraction of the latter may alone be evident. In addition, the increased excitability to the galvanic current found in complete De R (degeneration reaction) is usually absent. I have generally succeeded, however, in detecting the slowness of contraction of the atrophic fibres by using a mild current, which will produce a barely visible contraction of the healthy fibres. This phenomenon may also be made evident, even when the contraction appears of normal rapidity, by comparing the contractions with those produced in healthy parts. In some cases this is the only change noticeable. In others we also find predominance of An Cl C, or a tendency to tetanus during the passage of the current. When an exacerbation of the paralysis takes place very quickly, as sometimes happens, and is followed by rapid atrophy of the muscles, the latter may present all the changes of complete De R. Diplegic contractions have also been observed by a few writers. This term is applied to the following condition: When a small anode is placed in the mastoid fossa, and a broad cathode between the scapulæ, muscular contractions are observed in the arm opposite to the anode. These diplegic contractions are regarded as a reflex phenomenon, but possess no diagnostic importance, as they are also observed in other conditions.

The cutaneous and tendon reflexes are lost very early, even after comparatively slight atrophy of the muscles.

The integument over the atrophied limbs is usually cool to the touch, and pale. Trophic changes in the skin are rarely observed. Gowers refers to a case in which the skin of the face became thin and smooth, so that the iris could be seen through the closed eyelids. Pemphigus vesicles have been seen upon the palm of the hand in this disease. The skin and nails are occasionally thickened, and the latter may become brittle and fissured. A scaly condition of the skin and a tendency to ulceration have also been noticed. Enlargement and tenderness of the joints are rare phenomena; they are noticed particularly in the phalangeal joints, but have also been observed in the shoulders. I have seen a similar condition in the metatarsus during the early stages of the disease.

Excessive local diaphoresis has been reported in a few cases.

Among the rare phenomena noticed we may also mention the oculo-pupillary changes (contraction of one or both pupils, slow reaction to light), which are probably due to direct injury to the cilio-spinal centre in the cervical cord, and not to an affection of the sympathetic.

In the majority of advanced cases the temperature of the skin is lowered over the affected parts, but in rare cases there is distinct elevation of temperature—some-

* This term is a misnomer, since the contractions involve fibres or bundles of fibres; the term fascicular would be preferable.

times as much as five degrees—in the atrophied regions. Grasset has observed local elevation of temperature, associated with redness and sweating, confined to the palmar surface of the first phalanx.

In equally rare cases there is slight œdema of the hands and forearms, perhaps as the result of impairment in the circulation. These parts sometimes appear swollen from the increased development of subcutaneous fat.

Micturition and defecation remain normal throughout the entire course of the disease, unless the abdominal muscles are seriously wasted. In three cases Rosenthal found a diminution of kreatinin in the urine. Slight diminution in the amount of urea has also been noticed. Frommann reports large deposits of carbonate of lime, which he attributes to absorption from the atrophied muscles.

The disease always runs a slow, chronic course, and twenty or thirty years, or even more, may elapse before the fatal termination. In some the process spreads continuously, in the majority a remission occurs after a certain amount of progress has been made. This remission may last a variable period, from a few months to a number of years. Even a permanent arrest of the disease has been reported. In rare cases the process is attended with sudden exacerbations. The patient suddenly suffers from a considerable increase of paralysis in a certain limb, and this is followed in a few days by rapid atrophy of the paralyzed muscles.

In a not small proportion of cases the disease may become complicated at any stage by bulbar paralysis, or the latter may precede the former.

Death usually results from this latter complication, or from diseases of the respiratory organs aggravated by paralysis of the muscles of respiration; more rarely from intercurrent affections.

Pathological Anatomy.—The affected muscles are pale, and it may be difficult to distinguish any muscular structure in them. Under the microscope the changes are found to be confined almost exclusively to the muscular fibres. The capillaries of the interstitial connective tissue may be enlarged, the nuclei increased in number, and the fibrous tissue may present hyperplasia. Normal muscular fibres may be seen among others which are very materially altered. Some fibres simply appear to be narrowed. When this simple atrophy is far advanced, the hæmoglobin in the fibre may disappear; in other cases pigment may be deposited within the fibres as yellowish and brownish granules. In others the transverse striæ are less distinct, and the fibre is studded with minute granules of fat which in places have coalesced into larger or smaller globules. In advanced stages the entire fibre may be converted into a mass of fat globules. The longitudinal striæ sometimes become very much more distinct than the transverse striæ, giving the fibre the appearance as if it were split longitudinally.

An important feature is the extreme rarity of hypertrophy of the fibres. W. Mueller seems to have been the only one who observed, in addition to the presence of atrophied fibres, decided hypertrophy of other fibres. Fibres presenting very serious changes may be found alongside of others which are apparently normal.

Our knowledge of the pathological anatomy of this disease, in perfectly uncomplicated cases, is extremely meagre. The majority of autopsies refer to cases which were complicated with bulbar paralysis, but we hold that such cases are as decisive with regard to the pathology of the affection as the uncomplicated cases. As we shall see later on, the process in both affections differs only in regard to localization.

Struempell has described the post-mortem appearances in an uncomplicated case as follows: The spinal cord, as a whole, was narrow. Atrophy of the anterior horns and disappearance of the ganglion-cells in these parts in the cervical region were observed very distinctly in numerous preparations. The left lateral column was free. Slight atrophy of the cells existed in the lumbar region. In this case the atrophy was limited almost exclusively to the arms and shoulders, especially on the left side.

In Pierret-Troisier's case there was found degeneration of the ganglion-cells of the anterior horns, particularly on the right side; this horn was shrunken. The anterior nerve-roots were atrophied and contained numerous extremely fine nerve-fibres; some of the latter contained fat-granules. The white substance of the cord was normal.

In the large majority of cases, however, the spinal lesions were not confined exclusively to the anterior horns, and most of these cases present various symptoms which do not form part of the clinical history of pure spinal progressive muscular atrophy.

In a case in which, in addition to the usual symptoms of the disease, the patient suffered from severe paroxysms of pain in the lower limbs and violent muscular twitchings, Charcot and Gombault observed the following post-mortem appearances: There were profound alterations in the anterior horns of the cervical and dorsal cord (the atrophy had involved the upper limbs, neck, and back). In the lower part of the cervical enlargement there was almost complete disappearance of the ganglion-cells and of a great part of the nerve-fibres in the anterior horns. The dimensions of the anterior horns were not lessened to a notable extent, probably because there was such an enormous development of capillaries in this region. The lateral and posterior columns were intact throughout. There was sclerosis of the anterior root-zone in the cervical and dorsal regions. This sclerosis corresponded closely in degree with the lesion of the anterior horns, and was regarded by the authors as secondary to the latter. There was thickening and manifest inflammation of the pia mater at the emergence of the anterior roots. This was also observed over the remainder of the pia mater, but diminished posteriorly. There was a narrow zone of cortical sclerosis over the antero-lateral portion of the cord. The anterior nerve-roots of the cervical and dorsal regions were almost entirely destroyed.

Numerous cases have been reported in which sclerosis of the pyramid tracts was found in addition to the lesion of the anterior horns. These cases should be included under the heading of amyotrophic lateral sclerosis, and will be found discussed in the article on that subject in this volume.

Post-mortem examination has shown, however, that the intensity of the lateral sclerosis varies more or less in different cases, and that these variations correspond to differences in the severity of the spastic symptoms which are associated with those of progressive muscular atrophy.

In order to secure a better understanding of the subject, the question of diagnosis will not be discussed until we have described the clinical history of the myopathies.

Prognosis.—The outlook is always unfavorable so far as regards recovery, and if the disease becomes complicated with bulbar paralysis, it is always fatal. The most that can be hoped for is cessation of the advance of the atrophy, or perhaps slight improvement. If the disease does not attack the respiratory muscles life may be prolonged for many years, but, as a rule, the patient is finally reduced to a helpless condition.

Treatment.—The majority of authors recommend gentle exercise, but it has seemed to the writer that complete rest answers best in these cases. At all events, we feel quite sure that this is true with regard to the wasted muscles. The only exercise to which these muscles should be subjected is that secured by the use of the interrupted galvanic current, which may be applied directly to the parts. The current should be mild and the sittings of short duration.

The application of galvanism to the spine has also been recommended. This is done by placing both electrodes (large sponges) over the site of disease in the spinal cord, a mild uninterrupted current being applied for five or six minutes every day, or every other day. The sittings must be long continued, but even then we rarely obtain any decided benefit. Massage may also be employed, but should be discontinued if it is followed by disagreeable sensations in the wasted muscles. Arsenic and strychnine have been administered internally, but do

not seem to be of much benefit. Gowers states that he has obtained the best results from hypodermic injections of strychnine, beginning with gr. $\frac{1}{85}$ once a day and gradually increasing the dose to gr. $\frac{1}{40}$. But even this writer does not claim to have done more than check the progress of the disease.

GLOSSO-LABIO-LARYNGEAL PARALYSIS. — Synonym: Progressive bulbar paralysis. *Etiology.*—Hardly anything is known concerning the origin of this disease. It is much more rare than progressive muscular atrophy. It appears to be more frequent in the male than in the female sex. Among eight cases of which the writer has kept notes, five occurred in men, three in women. In three of the cases (two males, one female) the disease was complicated with progressive muscular atrophy. In one of the cases the affection began at the age of thirty-two years, in the others between forty and sixty years. It is rarely observed before the age of thirty-five years. Heredity seems to exert no influence in the development of the malady, and nothing whatever is known concerning other predisposing causes.

We also possess very meagre information concerning the exciting causes of the disease. A number of cases have been attributed to injury, excessive exertion of the implicated muscles (blowing on wind instruments), depressing mental emotions, colds, and constitutional syphilis. But the influence of any of these factors is very problematical.

Clinical History.—The disease generally begins without any prodromal symptoms, though the patients sometimes suffer from pains in the back of the neck and shoulders. As a rule, the first symptoms are those of slowly advancing paralysis and atrophy of the tongue. The patient begins to experience a certain degree of difficulty in articulation, especially of those consonants which are produced by the escape of air between the tip of the tongue and the upper incisors, or the anterior part of the hard palate (*d, t, l, n, s*). As the paralysis of the tongue increases, the difficulty in articulation increases *pari passu*, and finally speech becomes wholly unintelligible. When this stage is reached, the tongue usually lies as an inert mass upon the floor of the mouth, and sometimes cannot be moved voluntarily to the slightest extent. Fibrillary contractions in the organ are often noticed from the very beginning. Atrophy of the tongue keeps pace with the paralysis. On account of the unequal distribution of the atrophy, the surface of the organ presents depressions here and there. The organ is diminished in length as well as in its lateral dimensions. I have seen this so marked that the patient was no longer able to grasp the tip of the tongue and draw it forward. The paralysis of the tongue also interferes with mastication and deglutition. On account of the inability to perform lateral movements of the organ, the patient is unable to remove the food from between the teeth and cheeks with the tip of the tongue, and generally uses the finger for this purpose. The interference with the movements of the base of the tongue also causes difficulty in conveying the bolus of food into the pharynx.

The paralysis of the tongue has usually not advanced very far before the lips become affected. In some cases, indeed, both parts appear to be attacked almost simultaneously. This is first shown by interference with the articulation of those sounds whose production depends mainly on movement of the lips (*p, b, f, v, m, o, u*). At the same time there is difficulty in whistling, etc. If the finger is inserted between the lips and the patient is directed to contract the parts in order to compress the finger, it will be found that this is done with much less vigor than in the normal condition. The coincident atrophy of the lips usually becomes distinctly visible after a while, though this does not always happen. But the atrophy of the orbicularis oris can always be detected by grasping the lip between the thumb and index-finger, and thus determining its thickness. When the atrophy has made considerable progress, the mouth is kept half open, and the saliva is constantly dribbling. This is partly owing to the fact that the presence of the saliva no longer gives rise to the involuntary reflex movements of deglutition, by means of which it is conveyed into the œsophagus, and the secretion therefore makes its escape anteriorly. Careful measurements, however, have shown that the quantity of saliva secreted in twenty-four hours is often much larger than normal. This has been attributed by some to irritation of the salivary centre in the medulla oblongata.

The muscles of the chin are usually attacked about the same time as the orbicularis oris, and the corresponding movements of the lower lip are lost in consequence. Other facial muscles are very rarely affected, those inserted into the mouth (buccinators, levatores labii) being involved more frequently than the upper facial muscles. In rare instances, however, all the external facial muscles are paralyzed, and the face then presents the appearances of double peripheral facial paralysis.

The affection of the facial muscles gives rise to a peculiar change in the physiognomy. On account of the

FIG. 3647.—Case of Bulbar Paralysis Complicated with Progressive Muscular Atrophy.

unopposed action of the muscles inserted into the angles of the mouth and the upper lip, the latter is elevated and the mouth made wider. At the same time the naso-labial folds are constantly deepened. The lower lip, on the other hand, droops from its own weight. As a result, the patient constantly has a mournful expression of the lower half of the face, and this is heightened during laughter by the contrast between it and the upper part of the face, which retains its mobility. (Fig. 3647.)

Shortly after the development of the affection in the tongue and lips, the symptoms of paralysis of the pharynx and larynx begin and slowly progress. The muscles of the soft palate become paretic and the pillars of the fauces hang lower than normal. The posterior nares can no longer be closed perfectly during deglutition, and fluids are apt to regurgitate through the nose. For the same reason air escapes through the nose when the patient speaks, and speech assumes a nasal character. This also increases the difficulty in the articulation of labials, because a sufficiently strong current of air cannot be sent through the mouth to produce vibration of the lips. In the earlier stages of the affection this can be remedied to a certain extent by closing the nostrils, so that the entire current of air is forced to pass through the mouth. The paralysis of the pharyngeal constrictors increases still further the difficulty in deglutition. The

interference is first noticed with regard to solid food, so that the patient is compelled to confine himself to semi-solid, and then to purely fluid, articles of diet.

The laryngeal muscles are usually the last to be affected. The constrictors of the glottis are first attacked. The consequent inability to close the glottis permits the entrance of particles of food into the trachea and bronchi, and this may be followed by lobular (foreign body) pneumonia. At the same time the inability to close the glottis necessarily prevents vigorous cough, and may thus prove a very serious matter in the course of otherwise mild diseases of the lungs or bronchi. The muscles moving the vocal cords may also be attacked in comparatively rare cases ; this condition may be recognized during life with the aid of the laryngoscope. In such patients the voice becomes feeble and hoarse, and, finally, complete aphonia may result, although this is exceedingly rare.

The dangers arising from the paralysis of the pharyngeal and laryngeal muscles are increased still more by the fact that there is very often an early impairment of reflex action after stimulation of the mucous membrane. Krishaber has reported two cases in which this symptom was a premonitory manifestation of the disease.

In rare cases other nerve-tracts are also attacked. This is seen most frequently in the muscles of mastication (motor root of the fifth nerve). The masseters and temporals then undergo atrophy, and mastication is still further interfered with. The atrophy of the temporals is visible to the naked eye, and that of the masseters may be felt by grasping the muscle between two fingers inserted in the mouth.

Paralysis of the ocular muscles has also been noticed in rare cases, and may result in strabismus or ptosis. As a matter of course, the atrophy of the ocular muscles can only be inferred from their loss of function.

The electrical reactions of the paralyzed muscles are obtained with difficulty. The hypoglossal nerve is best reached by applying one electrode to the back of the neck, the other (small) electrode above and behind the hyoid bone. It is usually preferable to apply the small electrode to the tongue itself—this should be protruded as far as possible—and direct application may also be made to the velum palati and pharyngeal constrictors. Few patients, however, would consent to the latter manipulation.

The electrical irritability of the muscles, according to many writers, is simply diminished, but direct electrization of the tongue and lips will usually show partial degeneration reaction. Sometimes the formula of reaction is unchanged, and there is merely delayed and prolonged muscular contraction. Even this change may be so slightly marked, that comparison with healthy individuals is necessary in order to detect the deviation from the normal rapidity of contraction. Diplegic contractions are sometimes obtained in this disease as in progressive muscular atrophy.

Sensation remains unaffected in the mucous membrane covering the paralyzed muscles. At the most there may be slight aberrations of the sense of taste, but this can be explained by the fact that the mouth is generally lined with thick, glairy saliva, and that the tongue is usually coated.

Headache is occasionally a prominent symptom. The pain is referred usually to the frontal or occipital regions. Severe pains are also experienced occasionally in the back of the neck, particularly in those cases which are complicated with progressive muscular atrophy.

The disease usually runs a slowly progressive course, and lasts from two to five years. In some cases quite sudden exacerbations are observed. Remissions are also possible. In a case under the writer's observation at present, the first symptoms appeared more than six years ago. Soon after the patient came under treatment (five years ago) the symptoms began to improve slightly, and have remained at a standstill for the last three years.

But such a course is entirely exceptional. The patients gradually grow weaker and weaker, and finally die of inanition, perhaps accelerated by "foreign-body pneumonia," resulting from the aspiration of food into the air-passages. In certain patients respiratory and circulatory symptoms are observed in the later stages of the disease. Without any apparent exciting cause, severe attacks of dyspnœa suddenly develop and may even prove rapidly fatal from suffocation. The causation of these attacks is obscure.

In other cases the pulse is excessively slow, or it may be so rapid that it can hardly be counted. The patient suffers often from palpitation of the heart. This symptom is undoubtedly due to the spread of the bulbar lesion to the nucleus of the pneumogastric. Syncope ensues, but usually disappears very quickly, to reappear sooner or later. The patient may pass safely through a large number of these attacks, but they are not infrequently the immediate cause of death.

Bulbar paralysis is often complicated by progressive muscular atrophy or amyotrophic lateral sclerosis. The symptoms of the former affection may either precede or follow those of the latter.

The intellect is usually unaffected throughout the entire course of the disease. But the patients generally recognize the hopelessness of their condition at an early period, and exhibit a tendency to weep on very slight or no provocation.

In the large majority of cases the muscles are attacked in a typical order—first the tongue, then the lips, finally the velum palati, and the pharyngeal and laryngeal muscles. In exceptional cases, however, this order is not maintained. Duchenne observed paralysis of the velum palati and lips prior to that of the tongue, and this sequence has been seen by others.

Pathological Anatomy.—In the majority of cases the medulla oblongata, the site of the disease, appears unchanged to the naked eye. In some cases, however, the organ appears somewhat smaller than normal, and presents peculiar depressions in the floor of the fourth ventricle. As a rule, macroscopic changes are noticeable in certain of the bulbar nerves, the hypoglossal, facial, pneumogastric, spinal accessory, sometimes the glosso-pharyngeal, in rare cases in the motor root of the fifth nerve and the abducens. The nerves in question are smaller than normal, and have a grayish, translucent look.

Under the microscope the changes are very pronounced. They may be confined exclusively to the nuclei of the nerves mentioned above and their intra-medullary nerve-tracts, or the white matter may also be implicated to a certain extent.

As we are led to expect from the clinical history of the disease, the lesion is most marked in the nuclei of origin of the hypoglossal nerves. The ganglion-cells in this region present all stages of atrophic degeneration. Some have merely lost their prolongations and have become more rounded, and perhaps the nucleus is recognized with difficulty. Or, in addition, the protoplasm of the cell contains an unusual amount of brownish or yellowish pigment. In the most advanced stages the cell is merely represented by a shapeless mass of pigment, its original structure being entirely lost. Between these two extremes is found every possible gradation. The changes usually diminish in intensity from within outward.

Some observers have also described changes in the neuroglia and blood-vessels surrounding the ganglion-cells. The neuroglia may be increased in amount and present a more fibrillated structure than normal. In comparatively recent cases it sometimes contains compound granular corpuscles. The walls of the blood-vessels may be thickened, their nuclei increased, and the surrounding lymphatic spaces may contain an increased number of round cells.

Similar changes, though usually less pronounced, are found in the nuclei of the pneumogastric and spinal accessory nerves, the inferior nucleus of the facial, sometimes in the glosso-pharyngeus, trigeminus, and abducens. It is a peculiar and significant fact that the nucleus of the acoustic nerve always escapes, so far as I have been

Spinal Cord.

able to ascertain from a quite careful review of the literature of the subject.

In a large proportion of cases analogous lesions are found in the ganglion-cells of the anterior horns of the cervical cord.

But the lesion is not confined, in very many cases, to the ganglion-cells of the medulla. Déjerine has collected the reports of twenty-two cases of bulbar paralysis, and found that in the majority there was sclerosis or atrophic degeneration of the pyramid tracts. This is usually most marked in the medulla, and diminishes in intensity in an upward and downward direction. In two cases Déjerine found that the lesion extended into the cerebral peduncles, and was entirely similar in appearance and localization to the descending degeneration occurring after a lesion of the motor tract in the brain.

Under the microscope the affected nerves are found to contain an increased number of narrow fibres, and some fibres may even disappear completely, leaving merely the empty sheath. Granulo-fatty degeneration is also visible in some fibres. There is no notable change in the interstitial tissue.

The paralyzed muscles present the same appearances under the microscope as in cases of progressive muscular atrophy.

Diagnosis.—The diagnosis of chronic progressive bulbar paralysis is usually not a very difficult matter. The symptoms of acute bulbar paralysis resulting from hæmorrhage, thrombosis, or embolism of the medulla oblongata, are very similar to those of the chronic affection under consideration, but a mistake is prevented by the acuteness of the onset—usually as sudden as a stroke of apoplexy, though sometimes a few days may elapse before the bulbar symptoms are fully developed in cases of thrombosis. Even if we should be unable to obtain the clinical history of the disease, a mistake may be avoided from the fact that the paralysis, in acute bulbar lesions, is disproportionate to the muscular atrophy. In addition there is very often hemiplegia of motion, while sensory disturbances are also very apt to be present.

Tumors of the medulla, which are fortunately very rare, are excluded with greater difficulty, because they usually grow very slowly (the majority of these tumors are solitary tubercles). In the beginning the diagnosis may be almost impossible, but the tumor soon gives rise to compression of adjacent parts, and to general cerebral symptoms, and thus enables us to exclude bulbar paralysis. The symptoms of compression consist of paralyses of motion and sensation in the limbs, along the course of distribution of the bulbar nerves, of mellituria, etc. The general cerebral symptoms consist of headache, choked disk, vomiting, etc.

Pseudo-bulbar paralysis is the term applied to a bulbar complex of symptoms, which is due to lesions in other parts of the brain. It is usually the result of bilateral lesions of the internal capsule, corpus striatum, etc., but Kirchoff observed a case in which the bulbar symptoms resulted from embolism of the right middle cerebral artery, with secondary softening of the right corpus striatum, lenticular nucleus, and internal capsule. Barlow has also described a similar case, in which the bulbar symptoms followed embolic softening of the lower portion of the central and adjacent convolutions of one side. These cases can generally be excluded by the sudden onset of the symptoms, which are usually attended with cerebral disturbances, and by the absence of atrophy in the muscles or of changes in their electrical excitability.

Diplegia facialis (bilateral facial paralysis) could only be mistaken for bulbar paralysis on the most superficial examination. The patient, it is true, suffers from paralysis of the lips and disturbance of deglutition, on account of the food slipping between the cheeks and teeth; but the movements of the tongue and pharyngeal muscles are not interfered with, and the facial paralysis affects all the muscles of the face.

Oppenheim has reported a remarkable case of unavoidable error in diagnosis. The patient, twenty-nine years of age, first suffered from weakness in the hands and legs, then from difficulty in speaking and paresis of the lips, finally from difficulty in deglutition. There was also difficulty in opening and closing the mouth, and imperfect motion of the velum palati during phonation. Attacks of dyspnœa occurred subsequently, and speech became exquisitely bulbar in character. The tongue could be moved in all directions, but with difficulty. Electrical reactions were normal. On autopsy, nothing was discovered in the muscles, nerves, or central nervous system.

It is difficult to say how a mistake could have been avoided in this remarkably obscure case. Perhaps the absence of changes in electrical excitability might have aroused suspicions.

Prognosis.—Bulbar paralysis is almost always fatal. A few cases have been reported in which very marked improvement or even recovery has been reported, but this mere fact casts a doubt upon the diagnosis. Even a standstill which lasts more than a few months is a rare event. We may mention, however, that the patient shown in Fig. 3647 has fully held her own for the last two years. The patient either dies slowly from inanition, or death may occur suddenly from one of the accidents described in the section on Clinical History.

Treatment.—In a disease of this nature our therapeutic resources are utterly useless. Chief attention should be paid to the prevention of inanition, fluid food being administered through the œsophageal sound as soon as the disease has advanced to such a stage that there is danger of the entrance of food into the larynx and trachea.

Galvanization has been recommended in the form of stabile transverse currents through the medulla, one electrode being placed on each mastoid process, or movements of deglutition are produced by placing the anode on the back of the neck, and the cathode (with interrupting handle) on the side of the larynx.

Strychnine, iodide of potassium, and nitrate of silver have been recommended, but no good results are ever obtained from any method of treatment.

Pseudo-hypertrophic Paralysis. — *Etiology.* — In very many cases this disease has an hereditary basis. It often appears in brothers and sisters at about the same time in life. Meryon described eight cases in one family, Gowers four in one family. The writer has seen four (sisters) attacked in one family, two (brothers) in another. The hereditary influence is always transmitted by the mother, despite the fact that the disease generally attacks the male sex.

Age is another powerful predisposing factor, the disease almost always beginning during childhood. It is generally observed between the ages of two and five years, and is often noticed as soon as the child begins to walk. In rare cases, adult life is reached before the disease manifests itself. Among 100 cases collected by Seidel, 94 began before the end of the fifteenth year.

Sex also exerts a potent influence, boys being attacked much more frequently than girls. Among 220 cases collected by Gowers, 190 occurred in boys, 30 in girls.

Hardly anything is known concerning the exciting causes. A few cases have been found to develop after acute infectious diseases, exposure to wet and cold, and injury, but it is difficult to determine whether there is any real connection between the two series of events.

Clinical History.—The first indication of the disease is very often the tardiness with which the child begins to walk. This ability is acquired very slowly, and the child is soon tired by the exertion. If he has learned to walk before the onset of the disease, it is found that his gait loses in freedom and vigor, he becomes unable to run with ease, or to go up and down a flight of stairs, and finally even walking is attended with difficulty. At the same time the lower limbs begin to grow larger. The apparent hypertrophy may begin simultaneously in both calves, or it may first attack one, later the other. From the calves the pseudo-hypertrophy usually extends to the thighs (chiefly the anterior muscles) and the glutei. The lumbar muscles are very often the next to be attacked, or they may appear to be feeble from the start. Coincident with the enlargement of the various muscles is dim-

inution in their power. The enlargement often spreads to the muscles of the upper limbs, though these are more often wasted, and present a striking contrast to the excessive proportions of the lower limbs. The shoulder muscles are very often affected, particularly the deltoids. The muscles of the arm may be enlarged, but are also often wasted; those of the forearm usually escape for a very long time. The small muscles of the hand are hardly ever attacked.

The face is also involved in rare cases. The masseters may be enlarged, and the same condition has been observed in the tongue.

The enlarged, as well as the atrophied, muscles suffer diminution of power, and this gives rise to characteristic symptoms.

FIG. 3648.—Pseudo-hypertrophic Paralysis.

Until recently it was supposed that fibrillary contractions in the affected muscles never occur in this disease, but, as we shall see later on, there are some exceptions to this rule. This is also true of the degeneration reaction. As a rule, however, there is merely diminution of faradic and galvanic contractility. Sensation remains undisturbed throughout the disease.

After it has lasted a variable length of time, wasting appears in all of the hypertrophied muscles. The disease is slowly progressive, and death generally results from pulmonary affections, the gravity of which is increased by the muscular weakness, or from some other intercurrent disease.

We will now give a more detailed description of the individual symptoms.

Enlargement of the calves is usually the first symptom noticed, though sometimes the awkwardness and clumsiness of gait first attract attention. On the other hand, the size of the gastrocnemii may remain unchanged for a considerable time, despite the steady advance of the anatomical changes in the muscles. The enlargement of the calves is sometimes extremely great, and they may even attain a size of fifteen or sixteen inches in a boy ten years of age. The power of these muscles usually diminishes in inverse proportion to their increase in size, but their vigor sometimes remains approximately normal for quite a long time. True hypertrophy of these parts has been observed in rare cases.

The anterior leg group of muscles is not often enlarged, but the loss of power is usually more marked than in the calf. As a result, contracture of the latter takes place, and the heel is constantly drawn up, so that the patient, while standing, cannot bring it to the floor, and it is difficult to bring the foot to a right angle with the leg by passive motion. The movements of flexion and extension of the foot are necessarily interfered with, and the patient separates the feet in walking to a greater extent than usual, in order to widen the base of support. The calf muscles may remain firm—indeed, they may even assume an almost stony hardness,—but they do not present the elastic resistance of normal muscle.

The muscles of the thighs, buttocks, and back are usually the next to be involved. In many cases the buttocks alone undergo hypertrophy, and there may then be a very striking contrast between the large calves and buttocks and the wasted thighs. The loss of power in these parts gives rise to very peculiar disturbances in the position of the body when the patient stands, walks, or rises from the recumbent position.

When the patient stands erect the heels are usually raised slightly—sometimes very markedly, as shown in Fig. 3648—from the floor, and the weight of the body is thrown farther forward upon the ball of the foot. In addition, the pelvis becomes flexed on the thighs, and this tends to throw the centre of gravity still farther forward. Hence the back is thrown backward in order to maintain a balance, and forms a very prominent curve in the lumbo-dorsal region (lordosis), so that a line dropped from the most prominent part of the dorsal spine often falls several inches behind the most projecting part of the sacrum. This peculiar deformity disappears, as a general thing, when the patient sits down, and is probably not due, as has been believed by the majority of writers, to paresis of the extensor muscles of the back. When the patient sits down the weight of the trunk can be felt to tilt the anterior superior spinous process of the pelvis upward, and, as this takes place, the lordosis disappears, the spine becoming straightened. It is much more probable, therefore, that the lordosis is due to the tilting forward of the pelvis on account of the weakness of its extensors, and not to the paresis of the extensors of the spine.

FIG. 3649.—Pseudo-hypertrophic Paralysis. Position assumed by the patient in attempting to rise from the floor.

Certain characteristic phenomena are also observed in the act of walking. When standing erect the patient assumes the position described above. Then, as the act of walking is begun, the pelvis is raised very high on the side of the swinging leg, in order to allow the drooping toes to clear the ground. At the same time the trunk is carried far over toward the active leg, in order to bring the centre of gravity within the ball of the foot, and thus an oscillation is produced which resembles the waddling gait of a duck. I am able, from observation in a number of cases, to confirm Ross' opinion, that this is the

result of contraction of the gluteus medius—this can be readily felt on applying the hand to the buttock during the act of walking—and not, as Duchenne and the majority of other writers have believed, of paralysis of this muscle. All the movements in walking are slow and deliberate, and the patient is often compelled, in advanced cases, to aid himself in maintaining his equilibrium by making balancing movements with the hands, like a rope-walker. As the disease progresses still further, locomotion becomes impossible, and the patient is confined to the bed or chair.

In rising from the floor to the erect position, the following peculiar manœuvres are adopted: The patient first rolls over on his hands and knees; then the body is brought into the position shown in Fig. 3649, this movement being effected in great part by extension of the arms, which raises the trunk from the ground, and thus allows the lower limbs to be brought, with comparatively little effort, into the partly flexed position. The patient next places the hands in succession above the knees (Fig. 3650), at the same time pushing back the thighs, thus straightening the lower limbs and elevating the trunk still further. The next movement is to place the hands

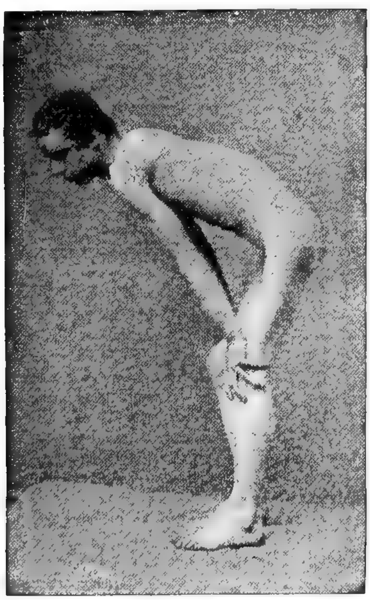

FIG. 3650.—Pseudo-hypertrophic Paralysis. Patient "climbing up his thighs" in the attempt to raise himself to the erect position.

on successively higher portions of the thighs ("climbing up the thighs") until the erect position is assumed. This peculiar method of assuming the erect position is not, however, pathognomonic of pseudo-hypertrophic paralysis, and I have often observed it in Pott's disease, whether in children or adults.

It is very rare to find hypertrophy so marked a feature in the disease of the upper limbs as in that of the lower, though cases have been described in which it was found in almost all the muscles of the body. In the upper part of the body the enlargement is limited much more often to certain portions. For example, the deltoids alone may be enlarged, or perhaps the deltoid and arm muscles on one or both sides. Hypertrophy has also been found in the muscles of the neck, back, and abdominal walls. The muscles of mastication (masseters and temporals) may be implicated in rare cases, and the tongue has been found a third larger than normal, so that deglutition and articulation were interfered with to a serious extent. According to Coste and Gioja, the latter condition was associated, in one of their cases, with the symptoms of hypertrophy of the heart. Gowers says that, next to the muscles of the calf, the infraspinatus is enlarged most frequently and markedly; the supraspinatus is also prominent at times.

But wasting is a much more prominent feature than enlargement in the affection of the upper limbs and trunk. This atrophy usually begins earliest and is most pronounced in the pectoralis major, particularly its lower half. The latissimus dorsi is also apt to be affected at an early period. According to Gowers, this is an important diagnostic sign and is sufficient to exclude the spinal form of muscular atrophy. Next, the scapular muscles undergo atrophy, and the process then creeps down the arms, the forearms being involved later and less frequently than the arms. The small muscles of the hand suffer in very few cases, and thus offer a striking contrast, in the majority of cases, to spinal progressive muscular atrophy. The muscles of the neck do not often undergo degeneration, though the process has been observed, in a few cases, in the sterno-mastoids. Even those muscles of the upper limbs which have undergone primary hypertrophy waste away after a comparatively short time. The diaphragm has, in a few cases, been found degenerated on post-mortem examination. When the atrophic process is far advanced in the upper limbs, the contrast with the enlarged lower limbs is especially striking. Paralysis of the muscles goes hand in hand with atrophy, and not only interferes with the specific movements of the upper limbs, but also with those movements of the lower limbs which had formerly been aided by the upper.

As the disease advances the patient finally becomes unable even to sit up, and is confined permanently to bed.

Fascicular contractions are hardly ever observed in this malady. In the rare cases in which they are present, they are not found throughout the entire course of the disease, and are not so apt to occur spontaneously, or with such frequency and vigor, as in spinal progressive muscular atrophy.

The electrical contractility of the muscles is usually diminished quantitatively, without any change in the mode of reaction. The diminution in the faradic and galvanic excitability, when the currents are applied directly to the muscles, seems to correspond with the diminution in the amount of normally acting muscular fibres. The electrical reactions through the nerves, however, are often stronger to both currents than when these are applied directly to the muscles. In rare cases partial degeneration reaction is observed in certain of the muscles. In Schultze's case, for example, distinct slow contractions were obtained in the left deltoid muscle with the galvanic current, and in addition the AnClC was more marked than the CaClC. Similar reactions were obtained in the first and fourth interossei and in the muscles of the thenar eminence. Other cases have also been reported in which the DeR was present. It must be remembered, however, that these changes in electrical excitability are very rare.

The patellar tendon reflex is usually diminished or lost at a comparatively early period, but this is merely the result of the loss of power in the quadriceps, and is not at all significant of any spinal affection.

Sensation may remain unaffected throughout the entire course of the disease. At first there are not infrequently vague pains in the lower limbs, and sometimes spasmodic twitchings in the calves, attended with painful sensations. After the disease has made some progress, the patient is apt to suffer from violent pains in the back, especially after he has remained in one position for a little while. The hypertrophied or atrophied muscles, especially the former, may be more or less tender on pressure.

The integument often presents a bluish-red, mottled appearance, particularly over the lower extremities. In these cases the skin is often cooler to the feel than normal. On the other hand, the integument of the hypertrophied calves sometimes has a higher temperature than that of the thighs or abdomen. Ord has observed an increased temperature of from one to two degrees.

Seidel has found that the increase in temperature produced by contraction of the degenerated gastrocnemius is from one to two degrees less than that resulting from contraction of the healthy muscles.

The functions of the bladder and rectum are usually intact, although obstinate constipation is not an infrequent symptom, especially if there is weakness of the abdominal muscles. The mental functions are commonly unaffected, but not a few patients are feeble-minded and even idiotic. Vigoroux reports a case which was complicated with Thomsen's disease.

The disease is slowly progressive, although there may be long intervals in which it is at a complete standstill. Even after the patient is confined helplessly to bed, he may linger for ten years or more. Death results generally from some pulmonary affection, such as bronchitis, phthisis, or pneumonia, which is aggravated by the feebleness of the respiratory muscles. In some cases even the intercostals become feeble, and this adds a new danger to any intercurrent lung affection. As a rule, death occurs within fifteen or twenty years from the inception of the disease, and few patients live beyond middle age.

Juvenile Progressive Muscular Atrophy.—This disease forms a clinical variety which, in typical cases, is quite distinct from other forms of progressive muscular atrophy of myopathic origin. It almost always begins before the age of twenty years, being most common in childhood. It is also often observed at puberty or during infancy. The hereditary element is the most striking feature in the etiology of this affection, and it occurs with comparative infrequency in isolated cases. Unlike pseudo-hypertrophic paralysis, it is not infrequent in girls.

Some writers believe that the pathological process in this disease is essentially distinct from that characteristic of pseudo-hypertrophic paralysis, but this position does not seem to be well established.

It begins generally in the shoulders and arms, sometimes in the lower limbs and back, and not infrequently in both localities at the same time. Throughout the disease atrophy of muscles constitutes the striking feature, but may also be attended with hypertrophy—sometimes true, sometimes false—in certain parts.

The atrophy, which is the first symptom, begins generally in the muscles of the scapula, shoulder-girdle, and arm proper; it then appears in the muscles of the back, buttocks, and thighs. The muscles below the elbow and knee are attacked late and with comparative infrequency. In the forearm, the supinator longus is most frequently affected, while the small muscles of the hand almost always remain normal, at least until a late stage of the disease. In the legs the peronei may be diseased at an early period, while the gastrocnemii long retain their normal bulk and power.

In certain parts, on the other hand, true or false hypertrophy of the muscles may be observed, the former appearing to constitute a compensatory process by which nature attempts to repair the damage done by the paralysis. These muscles include particularly the deltoids, gastrocnemii, supraspinatus and infraspinatus, the teres major and minor, triceps, and sartorius.

As in pseudo-hypertrophic paralysis, the pectoralis major, with the exception of the clavicular portion, and the latissimus dorsi are very constantly affected. The rhomboids, serratus magnus, biceps, brachialis anticus, supinator longus, and back muscles seem to be involved next in frequency to the pectoralis and latissimus dorsi.

When the disease attacks the lower limbs, it is found that the glutei, quadriceps, and anterior leg group, especially the tibialis anticus, are affected most constantly. The sartorius and gastrocnemii may escape for a long time, or may undergo true hypertrophy. Even in such cases, however, it is not uncommon to find that the hypertrophic muscles finally succumb to the atrophic process. A few cases have been reported in which the diaphragm and abdominal muscles also seemed to be involved.

Charcot has reported an interesting case in which the symptoms, so far as regards the distribution of the paralysis, corresponded exactly with Erb's juvenile form, but in which the bulk of the muscles did not undergo any change.

As in pseudo-hypertrophic paralysis, sensory disturbances remain absent, fibrillary contractions of the paralyzed muscles are observed very rarely, and there is simple diminution of electrical excitability to both currents, corresponding to the diminution in muscular bulk. The latter statement does not hold good in all cases, however, inasmuch as partial degeneration reaction may be present in certain muscles.

The disease may last from twenty to thirty years, or even longer, and its advance may alternate with periods during which the process seems to be kept in abeyance for years.

The following abstract of the history of a case (*vide* Figs. 3651, 3652, and 3653) now under the writer's observation, also furnishes an excellent illustration of the difficulties of diagnosis. For a number of years the patient had been regarded as a typical example of progressive muscular atrophy of spinal origin.

James M., forty-nine years of age. Family history negative. Patient had measles when ten years of age, typhoid fever at twenty-five; worked in iron works between the ages of eighteen and twenty-seven years. When twenty-seven years of age, after running two miles, he felt a lightness in the head and his sight left him for about ten seconds; he then vomited a good deal. He felt weak for a couple of days, but then returned to work. After this he would often feel stiff, sore, and weak in the back and legs after keeping still for a little while, but this would wear away after working. Two or three months later, he felt numbness in the tips of the fingers; this feeling would come and go. Weakness then developed in the right shoulder and arm, but the patient did not notice any wasting until two years had elapsed. Next the left arm grew weak, then the legs.

Fig. 3651.—Case of Juvenile Progressive Muscular Atrophy. (After a photograph taken in 1869.)

He entered Bellevue Hospital in 1869 (*vide* Fig. 3651, from a photograph taken at that time), and there gained sixty pounds in weight and grew somewhat stronger. At the end of a year he became slightly worse, and has grown rapidly worse in the last few years. The patient says the left calf has grown two and a half inches smaller in the last couple of years. He never saw any fibrillary contractions, but says that he has felt them during the last three or four years in various parts of the body, and also in the orbicularis palpebrarum.

Present Condition: Intelligence very good, nothing abnormal noticeable about the face or neck. Arms very much atrophied as compared with the shoulders and forearms. Right arm $8\frac{3}{4}$ inches, left arm $8\frac{3}{8}$ inches. Supination of left forearm is impeded as a result of old injury to the elbow. Right forearm $10\frac{5}{8}$ inches, left forearm $9\frac{3}{4}$ inches.

Right side: Hand, thenar and hypothenar eminences

Spinal Cord.

normal, flexion and extension of hand on forearm nearly, though not quite, normal; movements of fingers approximately normal. Flexion of the forearm on the arm is accomplished mainly by contraction of the supinator longus. Extremely feeble action of biceps and triceps. The deltoid is weak, but the arm can be raised to a horizontal position; trapezius well retained; no rhomboids can be seen or felt; the scapulæ cannot be approximated closer than seventeen and a half inches by voluntary effort. On the patient attempting to raise the arm, the lower angle of the scapula is separated more than three inches from the thorax. The latissimus dorsi appears to be lost. The supraspinatus seems normal, infraspinatus decidedly hypertrophied, but its power is somewhat diminished. Only a few fibres of the pectoralis can be felt.

Left side: Hand, slight depression over the dorsal interossei; diminished abduction and adduction of ring-finger; index-finger can be adducted fairly, but abduction is *nil*. Other movements of the fingers appear normal. The extensors of the wrist are much feebler than the flexors, and all the muscles of the arm are extremely wasted and feeble. The muscles of the shoulder and upper part of back are in about the same condition as those on the right side.

Fig. 3652. Front View of Same Patient. (After photograph taken in 1887.)

The deep muscles of the back can hardly be felt (there is considerable subcutaneous adipose tissue throughout the entire body). The glutei do not seem very much wasted, but have a doughy feel when relaxed. The patient can flex the thighs on the abdomen, but not with normal vigor. The quadriceps and hamstring muscles are very much atrophied on both sides. Right thigh, 17 inches; left thigh, 16½ inches. Adductors of thighs atrophied and flabby. Rotators seem moderately vigorous. Left anterior leg group very much wasted and soft, with corresponding diminution of power; right anterior leg group not much affected. Right calf muscles are a little soft, but not much wasted; those of the left leg are considerably wasted and paretic. Right leg, 13¾ inches; left leg, 12 inches. Slight patellar tendon reflex is present on both sides.

At the beginning of full inspiration there is slight sinking-in of the epigastrium, and the abdominal walls remain almost motionless. On forced expiration there is slight contraction of the abdominal muscles, most marked in the upper part of the recti abdominis.

While standing there is very marked lordosis, but this disappears in the sitting position and the back becomes straight. The lordosis is evidently owing to the tilting forward of the pelvis, thus necessitating a compensating curve in the dorsal spine to maintain the equilibrium.

The reaction of the wasted muscles to faradism is diminished throughout the body; this is also true, in the main, of the galvanic reactions, but certain muscles also present slight qualitative changes in galvanic excitability. In the triceps, for example, the muscular contraction is slow, and AnClC = CClC. This condition is also observed in the flexors of the left forearm.

The patient has the waddling gait of pseudo-hypertrophic paralysis, and rises from the sitting posture by "climbing up the thighs." Sensation is normal throughout the body; micturition and defecation are not interfered with. The disease has now lasted twenty-two years and, with the present slow rate of progress, the patient may live many years longer.

Infantile Progressive Muscular Atrophy.—Duchenne was the first to describe this affection, which he regarded as identical with spinal progressive muscular atrophy.

The disease usually begins about the age of five or six years, but it has also been known to begin in later youth, or even in adult life. As a rule, it first appears in the muscles of the face. The muscles attacked most constantly are the zygomatics and orbicularis oris. The wasting of these parts produces a peculiar change in the physiognomy. When the patient laughs the angles of the mouth are drawn upward instead of upward and outward, by the unopposed action of the levator labii superioris. At the same time the lips are kept slightly separated on account of the paralysis of the orbicularis oris, and the pronunciation of the labials is interfered with. The lower lip is pendulous and prominent, and often somewhat thickened. This latter symptom is not so constant, however, as has been supposed by the French writers. The face has a peculiar expression of mental hebetude, although intelligence is unaffected. In some cases the orbicularis palpebrarum, buccinator, and frontalis muscles also undergo atrophy. The tongue always remains unaffected, as do the muscles of mastication and those of the velum palati. Gowers has described a peculiar case which resembled the disease under consideration, and in which the ocular muscles were also paralyzed, but he was unprepared to make a positive diagnosis.

Fig. 3653.—Side View of Same Patient. (After photograph taken in 1887.)

The atrophy next attacks the shoulder and arm, and then spreads to the corresponding parts on the opposite side of the body. The shoulder-girdle and thoracic muscles are involved in turn, and finally the lower limbs, particularly the flexors of the thighs.

The forearms, with the exception of the supinator longus and the hands, are rarely attacked, though a few cases have been reported in which the muscles of the thenar and hypothenar eminences had entirely disappeared.

The supraspinatus, infraspinatus, and teres major and minor, are rarely attacked; the pectorals and latissimi dorsi are very commonly wasted.

The atrophy of the face may last five years, or even much longer, before any evidences of the spread of the disease become noticeable in the limbs or trunk.

In some cases the disease has begun in the arms or hands, and then spread, at a later period, to the face. This is especially apt to happen when the affection begins, as it rarely does, after the patient has arrived at manhood.

Hypertrophy of the muscles is never observed in connection with the atrophy, so far as I have been able to learn from the literature of the subject, with the exception of a case reported by Westphal, in which there was also pseudo-hypertrophic paralysis of the buttocks and thighs. As a rule, the electrical excitability of the affected muscles is simply diminished, but indications of partial DeR have also been reported in a few cases.

Heredity is the only known etiological factor in this rare disease. Duchenne reported, among others, two cases in a brother and sister; the father began to suffer from progressive muscular atrophy at the age of forty-eight years, but the face was not involved; the paternal grandfather had also suffered from some form of progressive muscular atrophy, which had advanced to such a stage as to render him entirely helpless. Westphal observed the disease in a woman who also suffered from paranoia, with periodical alternations between depression and exaltation and diabetes insipidus during the periods of exaltation.

In a considerable proportion of cases the disease does not run the typical course just described, and there are numerous transitions from one type to another. For example, Charcot has described a case in which the localization and course of the disease were similar to those of pseudo-hypertrophic paralysis, but the affected parts presented no increase in size. Again, Landouzy and Déjerine claim that the infantile form of progressive muscular atrophy is always attended by atrophy alone; but Westphal has described a case which was associated with marked pseudo-hypertrophy of the buttocks and thighs. In like manner I could show from the literature of the subject, did space permit, that there are transitions between all the varieties of myopathy, and it often depends upon personal bias whether the case is placed in one or the other category.

The disease may last very many years, and does not often prove directly fatal to life.

In concluding the clinical history of the various forms of progressive muscular atrophies, I will briefly refer to a peculiar variety, described by Charcot and Marie (Tooth has applied the term peroneal type to this affection), and which seems to occupy a position apart from the other forms. I will merely give a brief abstract of their paper (*Rev. de Méd.*, 1886, p. 97).

The disease always begins in the lower limbs, usually in the extensors of the great toe or the common extensor, or the peronei. This is the first noticeable symptom, though it is probable that the paralysis really begins in the intrinsic muscles of the foot, but escapes notice on account of the unimportance of these parts. All the muscles of the leg are gradually involved, the calves remaining unaffected longer than the other parts. Paralysis and atrophy go hand in hand, and finally become complete. The thighs continue normal for a certain length of time. The vastus internus seems the first to be attacked, the adductors are well preserved, and the flexors of the thigh are but little affected.

The hands become affected in from two to five years after the atrophy has begun in the legs. The change always appears first in the small muscles of the hands, and then extends to the forearms. The interossei are not always affected in a uniform manner. The extensors of the forearm usually suffer before the flexors; the pronators and supinators are attacked very late, if at all; the supinator longus is always normal. All other muscles remain intact.

Fibrillary contractions are very distinct, except in the last stage of atrophy. The direct muscular excitability is diminished in the affected parts, and this is true of the tendon reflexes.

In completely wasted muscles the electrical excitability is lost. In those less affected there is DeR; AnClC = or > CaClC, the contraction is slow, and faradic contractility is abolished. In slightly affected muscles there is simple diminished reaction to both currents.

The muscles do not undergo contracture; the integument of the affected parts presents well-marked bluish or reddish marbling. The subcutaneous adipose tissue may be increased. The temperature of the affected limbs is considerably diminished. These symptoms are less marked in the upper than in the lower limbs.

In four cases, sensation was undisturbed. In one of Eichhorst's cases there was hyperæsthesia of the dorsum of the foot; in another case there was diminished sensibility in the legs.

In one of Charcot's cases there was anæsthesia to touch and temperature, which became less marked in the upper part of the limb. There were also retardation and persistence of sensation, and the muscular sense was also slightly affected. This patient suffered from pains in the lower limbs.

Pains have also been observed in other cases, but do not seem to be an essential feature of the symptomatology. Cramps in the calves were noticed in almost every case. The other bodily functions were normal.

The disease generally begins in childhood or youth. Among 19 cases, 14 began before the age of twenty-two years. In one of Eichhorst's patients the disease was perhaps congenital; in another it began at the age of thirty-six years; in two of Wetherbee's patients, at thirty-nine years.

Pathological Anatomy.—A number of cases have been reported in which the most careful and competent examination failed to reveal the slightest evidences of change in the nerves or spinal cord. In a number of other cases slight lesions have been found in the spinal cord, but these were entirely disproportionate to the muscular disease, and were probably either secondary or mere coincidences.

"Granular disintegration" of various parts of the spinal cord has been observed a number of times by various English writers, but there is very little doubt that this lesion is an artefact, produced during the hardening of the tissues in alcohol.

Changes in the muscles, on the other hand, are found in all cases, but while the histological appearances are quite distinct from those described in spinal progressive muscular atrophy, those found in the various myopathies differ greatly from one another.

I will first give the results of my own examinations.

In a case of pseudo-hypertrophic paralysis, I observed the following: A large amount of adipose and fibrous tissue was situated between the muscular fibres. A few capillaries were found distended with blood, their walls thickened, and presenting nuclear proliferation. The vascular changes constituted a minor part of the morbid process. The muscular fibres were very markedly changed. They were very unequal in size, and few of them maintained the same dimensions throughout their entire length. A few fibres had a peculiar convoluted appearance, and a number branched dichotomously. In many the transverse striæ were indistinguishable, in others they were less distinct than the longitudinal striæ. Even in those fibres in which the transverse striæ were distinct, they did not seem to be as far removed from one another as in the normal condition. Some had a homogeneous swollen appearance (vitreous degeneration), and the sarcolemma had a jagged outline as if it were distended by its contents. In many places the muscle nuclei within the sarcolemma were increased in number, rounded, and only about a third the length of the normal nuclei. There was very great increase in the number of nuclei upon and around the sarcolemma.

In a case of Erb's juvenile atrophy the appearances were very similar to those just described, but not identical. The blood-vessels did not seem to be changed, but there were broad bands of fibrous tissue, containing numerous nuclei, and here and there a few clumps of adipose cells, running between the muscular fibres. The latter were very scanty and presented a striking contrast in size. The majority were very large, but a considerable proportion were much narrowed. Almost all had a vitreous appearance, but the striæ were distinct. In not a few there was transverse fissuring, and rarely longitudinal fissuring. No dichotomous fibres were seen, but there were a few convoluted ones. The nuclei within the sarcolemma were slightly increased.

In Schultze's case, which also resembled Erb's juvenile form, the increase of connective and adipose tissue between the muscular fibres was comparatively slight. Most of the latter were unchanged in size, but some were hypertrophied. There was increase of sarcolemma and muscle nuclei; the striæ were preserved; some of the hypertrophic fibres branched dichotomously. Schultze also observed a peculiar vacuolization of certain fibres. In some the vacuole included almost the whole width of the fibre, leaving only a small rim of muscle-tissue at the circumference. In others there were several vacuoles in one fibre, with a delicate meshwork of muscle-tissue between them.

In a case of atrophy with implication of the facial muscles (infantile progressive muscular atrophy), Westphal examined a piece of the left deltoid. He found simply hypertrophy of fibres (0.185–0.203 mm. wide, the normal width being 0.010–0.062 mm.), which otherwise looked normal; there was also some increase in the number of sarcolemma nuclei.

Gowers believes that the apparent hypertrophy is the result of "a vital contraction excited by the process of excision." This seems to be disproved by Schultze's case, in which the hypertrophy was observed on post-mortem examination, and not after excision in the living subject.

Hardly anything is known concerning the pathological anatomy of the peroneal type described in the section on clinical history. Charcot and Marie suggest that it is the result of peripheral neuritis, and in three cases interstitial neuritis was really found on autopsy. It must be admitted, however, that our knowledge of this affection is too imperfect to warrant us, for the present, in drawing any conclusions with regard to its pathology and pathological anatomy.

Pathology.—Extreme views are entertained with regard to the pathology of the affections under consideration. Some pathologists look upon them as being purely myopathic, others are inclined to regard them as purely central in origin. The majority of writers, however, look upon some of them as myopathic, others as myelopathic.

With regard to the pathology of bulbar paralysis, there can be very little doubt. It was long supposed, in accordance with the teachings of Duchenne, that this disease differs essentially from the progressive muscular atrophy usually regarded as spinal in origin, in the fact that the paralysis and atrophy of the muscles do not go hand in hand, the former being usually far advanced before the latter is appreciable. This statement is not in accordance with the facts, and the apparent discrepancy arises from the frequent difficulty of detecting atrophy in the affected parts. In more than one case I have remarked the failure of good observers to detect atrophy of the orbicularis oris in progressive bulbar paralysis, although this becomes evident at once as soon as the lips are grasped between the fingers, and the thickness of the muscular tissue is compared with that in healthy individuals.

In the tongue the atrophy is usually evident from a very early period in the disease. In all other respects this disease runs the same course as myelopathic progressive muscular atrophy, and the frequent combination of lateral sclerosis with one or both of the above-mentioned diseases points to the intimate relations between these three affections. Indeed, it seems very probable that they all are the result of one underlying cause, which, for some unknown reason, attacks only the motor system (one case of amyotrophic lateral sclerosis has been reported, in which not alone were the pyramid tracts involved in their entire course through the brain, but also the ganglion-cells of the motor cortical zone), and that, as the localization of the lesion takes place in one or the other locality, we shall find the symptoms of bulbar paralysis, progressive muscular atrophy, or amyotrophic lateral sclerosis.

The histological appearances of the paralyzed muscles also furnish a strong argument for the nervous origin of bulbar paralysis. Although our knowledge of the morbid anatomy of the muscles in the various muscular atrophies is still imperfect, nevertheless I think I am warranted in saying that the morbid appearances in those forms which are undoubtedly myopathic, are very different from those observed in paralyses of undoubted spinal origin, for example, acute anterior poliomyelitis; and also from those found in bulbar paralysis and the so-called spinal progressive muscular atrophy. The constant occurrence of the degeneration reaction is another important point in favor of the nervous origin of the disease. As we have seen in the section on clinical history, this is exceedingly rare in the various forms of myopathy, and has been observed hitherto only in lesions of the peripheral nerves or the anterior horns of the spinal cord.

The theory of the other school proves too much. If the spinal lesions, as is claimed, are secondary to the disease of the muscular system, there is no apparent reason why advanced stages of the latter should not always give rise to lesions of the cord. That this is not true is proven by numerous cases in which the central nervous system was found intact. This very fact seems to me to prove that the myopathic theory is insufficient for all cases.

The frequent combination of bulbar paralysis with progressive muscular atrophy points to the similarity of the two affections. Moreover, the clinical history is practically the same if we take into consideration the vital importance of the parts affected. In addition to the fact that the anterior horns of the spinal cord have been found diseased in pure cases of progressive muscular atrophy, we have the further fact that the symptoms of the disease are also observed in other affections of the spinal cord which extend to the anterior horns (deuteropathic).

We are therefore forced to the conclusion that bulbar paralysis and progressive muscular atrophy are due to primary lesions of the motor cells in the medulla oblongata and anterior horns of the spinal cord, respectively. The lesion in question is apparently of the nature of a simple atrophic degeneration, but some pathologists regard it as inflammatory in its nature. We possess insufficient data to decide this question, although I think the weight of evidence is in favor of the former view.

On the other hand, there are undoubted cases of primary myopathic disease, such as pseudo-hypertrophic paralysis and its allied affections, and it seems as if these latter diseases were more frequent than was formerly supposed. Many cases which were regarded as central in origin are now placed in the category of myopathic affections. But what the nature of the muscular lesion is I am unable to state. The theory of its inflammatory character does not seem to be in accordance with the pathological appearances. Nor is there, in my opinion, any satisfactory foundation for the theory that the changes in the muscular fibres are the result of compression, due to primary increase of the interstitial connective and adipose tissue. We may merely beg the question by saying that the disease is the result of a trophic disturbance in the muscular substance itself, resulting from a congenital or acquired anomaly of nutrition in the muscular system, and which probably gives rise secondarily to the changes which are observed in the interstitial tissue. We are also entirely in the dark with regard to the differences in the localization of the affection. It must be left to future investigations to decide whether these variations are the result of vital differences in etiology, or whether they are different forms of one disease. The prevailing opinion, at the present time, is very decidedly toward this latter theory.

The nature of the lesion in the "peroneal type" of muscular atrophy must be left for future investigations. We may say, however, that the strong hereditary element and the clinical history seem to indicate a peripheral, rather than a central, origin.

Diagnosis.—We will first consider the differential diagnosis of spinal progressive muscular atrophy from atrophy of myopathic origin.

The occurrence of fibrillary contractions is an impor-

tant sign. This symptom is quite constant in myelopathic atrophies, and until very recently it was supposed never to occur in the myopathic affections. We now know, however, that it is observed in rare cases of the latter. In myopathies, however, the symptom is not a prominent one, and does not appear to be of long duration.

The electrical reactions of the paralyzed muscles furnish another differential sign. As a rule, complete or partial (usually the latter) degeneration reaction is observed in myelopathic atrophy, even at an early stage of the disease. As we have pointed out in the remarks on symptomatology, this symptom may be elicited with difficulty when the healthy fibres in a muscle predominate over the atrophic ones; and if the latter are very scanty in proportion to the others, even the most careful examination may not disclose any change. In myopathic atrophies, on the other hand, simple diminution of excitability to both currents is the almost invariable rule, although recent observations have shown that partial degeneration reaction is present in some cases.

As a general thing, the diagnosis can be made from the manner in which the disease spreads from one part of the body to the other. Myelopathic progressive muscular atrophy begins almost invariably in the small muscles of the hand or in the shoulders, and then spreads to the muscles of the arms and trunk. In the myopathies, the small muscles of the hand are hardly ever attacked, even after the disease has lasted a long time and made great advances in other parts of the body. Furthermore, spinal progressive muscular atrophy usually attacks one muscle after another in such a way that we can follow its course, while the myopathic forms attack whole groups of muscles at apparently the same time. For example, the former disease will attack one interosseous muscle after another, then successive muscles of the thenar and hypothenar eminences, next the muscles of the arms, etc. But in the myopathic forms, for example in pseudo-hypertrophic paralysis, the patient will be found suffering, at the beginning of the disease, from weakness of almost all the muscles of the lower limbs and back, though some are affected more severely than others.

Heredity as an etiological factor is found almost exclusively in the myopathies, so that the occurrence of muscular wasting in more than one member of the same family is a strong argument in favor of its myopathic origin. The latter diagnosis is favored in an equal measure by the occurrence of the disease in childhood or youth.

Finally, the microscopical examination of excised portions of the affected muscles may throw some light on the diagnosis. In wasting of central origin, the muscle usually presents, at least for a long time, the evidences of simple degenerative atrophy; in myopathies hypertrophy of fibres is found in almost all cases, the transverse and longitudinal striation is usually quite well preserved, and interstitial changes are found at an early period.

In conclusion, it may be said that, while a careful examination of all the facts will generally enable us to decide between the muscular or central origin of the disease, in some the doubts can only be dissipated by post-mortem examination.

A few words with regard to the differentiation of spinal progressive muscular atrophy from other diseases of the nervous system.

At the onset of the malady the diagnosis of lead palsy is sometimes excluded with difficulty. The latter may begin apparently in the interossei and, in exceptional cases, the muscles of the thenar and hypothenar eminences undergo early atrophy. As a rule, however, the supinator longus escapes on the extensor side of the forearm, and the flexors remain normal, or approximately so. But if we remember that the wasting of lead palsy may also extend to the muscles of the arm and shoulder—indeed, sometimes to the lower limbs—and that DeR is present, it is evident that mistakes may arise. A case is at present under the writer's observation in which the interossei, thenar, and hypothenar eminences were first attacked, and for some time it was regarded as probably a case of progressive muscular atrophy. The patient has no blue line on the gums, no mode in which lead could have entered the system can be discovered, and chemical examination of the urine for lead was attended with negative results. The diagnosis of lead palsy was made on account of the previous occurrence of abdominal colic (without any ascertainable cause), the paralysis of the extensors without implication of the flexors, the complete DeR at an early period, and the comparative rapidity of improvement under treatment. In this case, as in a number of other undoubted cases of lead palsy, the supinator longus is also paretic, though not to such a marked degree as the extensors.

Deuteropathic progressive muscular atrophy, *i.e.*, that form of disease in which the atrophy results from the extension of a lesion in other parts of the spinal cord to the anterior gray columns, is distinguished from the protopathic variety by the presence of the symptoms of the primary disease (pains, anæsthesia, occurrence of paralysis before the development of atrophy, interference with the functions of the bladder and rectum, etc.).

After the diagnosis of myopathy has been made, the special variety is recognized by the localization of the wasting and hypertrophy of the muscles, and the course of the disease as described in the section on clinical history. A large number of cases, however, constitute transitions between the different types there mentioned, and cannot be definitely relegated to any special class.

Prognosis.—Complete restoration of parts which have undergone wasting or hypertrophy never seems to occur. In all cases, the chance that the disease will not shorten life is so much greater, the later the period at which the disease begins. When this takes place in adult life, the patient may live to an advanced age, unless carried off by an intercurrent disease. It must always be remembered, however, that diseases of the respiratory organs are a special source of danger in myopathies, on account of the frequent implication of the respiratory and abdominal muscles.

In pseudo-hypertrophic paralysis the lease of life is usually shorter than in the other varieties, but even here the disease may come to an apparent standstill for years. More rapid progress is often made after the patient is permanently confined to bed.

Treatment. — Pseudo-hypertrophic paralysis does not seem to be influenced by treatment. Massage and electricity have been recommended. Benedikt claims to have cured five cases by galvanization of the sympathetic, but his statements should be received with a great deal of caution. Uhde and Gowers have derived benefit from cutting the tendo Achillis when walking is prevented by contracture of the calf muscles. Duchenne reports two cases in which the disease was arrested by prolonged faradization of the muscles.

Better results seem to have been obtained by faradization and galvanization of the muscles in the other forms of myopathy, notably in Erb's juvenile form.

Leopold Putzel.

SPINAL CORD DISEASES: SPINAL HEMIPLEGIA.

Synonym: Brown-Séquard's Spinal Paralysis.—Spinal hemiplegia is the name, not of a disease, but of a group of symptoms, produced by unilateral lesions of the cord. Such lesions are in part of traumatic origin, such as gunshot wounds, or wounds with sharp instruments, resulting in partial destruction or section of one-half of the cord, the injury being limited to that side; in part the result of disease, as compression of one-half of the cord by a tumor, or blood-clot, circumscribed sclerosis, etc. Similar manifestations have been produced by experimental hemi-section of the cord in animals, especially at the hands of Brown-Séquard. It was the latter who first drew a clear picture of spinal hemiplegia, based partly upon his experiments, partly upon the analysis of reported clinical cases. Both the clinical picture and the physiological conclusions drawn from it, though often looked upon with distrust, are now pretty generally accepted Yet, future modifications of the physiological views are

not improbable. This is more likely to be true of the paths of the sensory fibres, the study of which has always met with great difficulties, than of the motor fibres, whose course seems to be pretty definitely determined. Modifications are the more probable, because the lesions of the cord upon which physiological views are based—experiments on animals are not now referred to, because their results are not always directly applicable to man—have rarely the precision necessary for exact conclusions, and observations in different cases have been, to some extent, at variance with one another.

The most prominent symptom is motor paralysis of only the lower, or of both lower and upper extremities, according to the location of the lesion. It is on the side of the lesion, though there is also, at times, slight paresis of the other side. There is often a temporary vaso-motor paralysis on the side of the lesion, indicated by a rise of temperature of the paralyzed limb. There is at the same time sensory paralysis—anæsthesia—of the opposite side of the body, while there is heightened sensibility—hyperæsthesia—on the side of the lesion. But this is only true of certain kinds of sensibility—that to touch, pain, temperature, etc.—while the muscular sense is abolished on the side of the lesion.

The physiological deductions from these clinical data are as follows: The motor fibres run in the cord on the same side as are the muscles supplied by them. They cross to the other side in the medulla oblongata. The slight paresis sometimes found on the other side is perhaps due to a small number of the motor fibres decussating with those of the opposite side in their passage through the cord, or, perhaps, each cerebral hemisphere is, to a certain extent, related to both sides of the body.

The sensory fibres pertaining to muscular sense also run through the cord on the same side, while all the other sensory fibres, very soon after their entrance into the posterior roots, decussate with those of the other side and run to the brain in the opposite side of the cord. Brown-Séquard believes that there are different nerve-fibres for the different kinds of sensibility—touch, temperature, pain, etc.—and that they lie in different parts of the cord; for there may be loss of one kind of sensibility and not of others, or one may be affected to a greater extent than the others. If this be true, those of pain and temperature are most nearly related, for they are usually affected to about the same degree.

The symptoms thus far given are those of severance or destruction of the nerve-strands in the cord. But there may be further symptoms dependent on injury of nerve-cells in the cord, or of the nerve-roots, or due to secondary degenerations. Destruction of the large ganglion-cells causes muscular atrophy. This atrophy is found in the muscles innervated from the level of the lesion. Destruction of the anterior nerve-roots also causes muscular atrophy; destruction of the posterior roots, anæsthesia. The latter is always on the side of the lesion. Therefore, on the side of motor paralysis the hyperæsthesia is limited above by an anæsthetic border. Secondary degeneration of the lateral columns below the seat of lesion causes muscular rigidity, exaggerated tendon reflexes, etc., in the parts affected by motor paralysis.

In some instances temporary paralysis of the bladder and rectum was observed. Rarer occurrences were acute decubitus on the side of sensory, and inflammation of the knee-joint on the side of motor, paralysis. After disappearance of paralysis of the lower extremity ataxia has been observed, probably due to injury of the posterior column. *Philip Zenner.*

SPINAL CORD DISEASES: SPINAL IRRITATION.

INTRODUCTION AND DEFINITION.—Although the complex of symptoms described by older authors under the name of Spinal Irritation has no pathological anatomy beyond the very probable one assigned to it by Hammond, of anæmia of the posterior columns of the spinal cord, the affection is, nevertheless, of sufficient importance, and is frequently enough met with, to deserve to be retained in the more recent nosology of nervous diseases. It is an affection characterized by acute pain in the spinal region, always increased by pressure over the spinous processes, and is associated with various disturbances of sensibility along the course of the spinal nerves, arising from the affected region, and with certain visceral functional derangements; the motor nerves are also affected, but in a lesser degree.

Spinal irritation is most frequently found in women between the ages of fifteen and thirty-five years. These subjects frequently present symptoms of hysteria, but the affection is often enough observed independently of the latter malady, and is occasionally seen in men, so that its distinct identity cannot be seriously doubted by anyone with moderate experience.

ETIOLOGY.—Among the predisposing causes of spinal irritation, sex comes first in order. As already mentioned, women are peculiarly liable to this affection, and those who show greater tendency to hysteria are more frequently attacked, but at times even the most phlegmatic become victims to it, and men are not exempt. This disease is most frequently seen between the ages of fifteen and thirty-five years, and therefore young adult life would seem to predispose to it; but it occasionally occurs at a later period, and even in old age, and it has been observed, though rarely, in childhood. The hysterical temperament, even in those who have never had any distinct hysterical attacks, must be considered as an efficient predisposing cause. Also, heredity plays an important rôle, the disease being very often met with in members of a neurotic family. In a number of cases the disease cannot be traced to any special cause. Anything that weakens or excites the nervous system may act as an exciting cause; such are strong emotions, violent passions, grief, fright, care, love, anxiety, mental over-exertion, etc.; also violent bodily exercises, excessive watching or working at night, forced marches, strains, falls, or blows on the back, insufficient physical exercise, abuses in venery, onanism, excess in the use of alcohol or tobacco, frequent ungratified sexual desires, bad food, and exhausting diseases, such as typhoid, malarial, and scarlet fevers, dysentery, diphtheria, etc.

Formerly affections of peripheral organs were credited with bringing on the disease in a number of cases, but this is no longer thought of.

SYMPTOMS.—The development of the disease is usually gradual, the first symptom being a slight feeling of discomfort, scarcely amounting to pain, somewhere over the spine, more generally in the dorsal region and between the scapulæ. This is at first felt only after unusual fatigue or exertion, but very soon becomes constant and amounts to severe pain. This pain varies considerably in intensity at different times and in different patients, and it is described as a sharp, burning, boring, or lancinating pain; it is always increased by pressure on the spinous processes of the vertebræ; occasionally the skin in the region of the pain is very hyperæsthetic, and contact with the clothing even is insupportable; at other times the pain in the back is so slight as to escape the patient's attention, who complains only of the excentric symptoms to be presently mentioned, and the pain is excited only by pressure over the spine. The location of the pain varies much in different patients, and in the same patient at different times; its most usual seat is the dorsal region, between the shoulder-blades, and the next most common locations are in the back of the neck, and, less frequently, in the loins; occasionally it is felt over the whole spine. Hammond, and others after him, describe a deep-seated pain over the other vertebræ, which is increased by pressure or movements of the spine.

Besides this pain, and more noticeable to the patient, are a number of excentric symptoms, more or less referable to disturbances of sensibility and of the functions of the vegetative organs, but also affecting, though to a lesser extent, the motor apparatus. The symptoms vary according as the pain in the back affects different portions of the spine. When the cervical spine is complained of we have neuralgic pains, and various paræsthesiæ, such as tingling, formication, and a feeling of heat or cold in the neck, chest, and upper extremities; at times vertigo, headache, noises in the ear, disturbances

of vision, fulness and a sense of constriction across the forehead, and tenderness of the scalp, especially in the occipital region. In some cases distinct disturbances of the functions of the mind, sleeplessness, etc., also nausea, vomiting, hiccough, palpitation, and pain in the stomach, fibrillary twitchings or stiffness, clonic or tonic contractions, or more or less violent choreic movements of the muscles of the arms and neck, and occasionally loss of power in the upper extremities. These symptoms are, of course, only in part present in each case, and vary considerably in intensity in different cases.

When the dorsal portion of the spine is complained of we have, besides pain and tenderness in that region, intercostal neuralgia, infra-mammary pain, gastralgia, nausea and vomiting, dyspepsia, gastric flatulence and acidity, heartburn, palpitations, and attacks of syncope, and some slight disturbances in the sensibility or motility of the lower extremities.

When the lumbar portion is affected the symptoms are tenderness in the lumbar spine, neuralgic pains, with formication and other paræsthesiæ round the abdomen and down the lower extremities, cold feet, at times spasm of the neck of the bladder giving rise to retention or incontinence of urine, costiveness, and pain in the rectum, uterus, and ovaries; also at times weakness of the lower extremities, or contractures, spasms, or clonic movements in the same.

When the whole spine is affected we have more or less a combination of the above, the symptoms being the most prominent in those regions which are supplied by the nerves arising from the cord at the point of the greatest spinal tenderness.

The symptoms of spinal irritation are, as a rule, alleviated by rest in a horizontal position.

Course and Duration.—The course of the disease can be inferred, from what has been already said, to be very fluctuating, improvement and relapses alternating in quick succession without any apparent cause, the chief symptoms sometimes rapidly changing and affecting different regions of the spine and body. Its course is in some cases very acute, the disease developing rapidly and terminating in the same manner. In most cases, however, it runs a chronic course, developing slowly, and is equally as slow in improving, lasting months, or even years, under the most efficient management. Some patients suffer more or less all their lives from some form or other of the affection. As a rule, however, a cure may be promised as a result of proper medical and hygienic treatment.

The question, "Can the disease lead to some more dangerous spinal affection?" may with safety, I believe, be answered in the negative, if we take into account the views of the more recent authors, who certainly have had better opportunities to study the disease, and who have not confounded it, as older authorities occasionally did, with organic affections.

As to the true nature of the affection, nothing is positively known; numerous hypotheses have been advanced to explain it, but none is absolutely proven. Some authorities claim that it is due to hyperæmia of the cord, while others, with Hammond, and I believe with some reason, assert that it is due to anæmia of that organ.

Case I.—C. B——, white, female, aged thirty-one; has been married two years, has one child living, does not belong to a neurotic family, gives no history of hysteria or any other nervous disease. She is a housemaid, but is much above her class in education, and is quite refined in manners, and evidently has seen better days. About a year before her application to me for treatment, the initial symptoms of her affection began to show themselves. After a period of prolonged grief she began to be troubled with an uneasy, painful feeling in the spine, about the upper dorsal region, after every severe exertion; this feeling soon became continuous, and was increased whenever she was accidentally touched on her back at that part of the spine: she was always easy at night, or when lying down. With the increase in severity of the pain she was also troubled with attacks of breathlessness and palpitation, and had a constant sharp stitch in the infra-mammary region on the left side. Her appetite soon began to fail, and she was greatly troubled with nausea and occasional vomiting; her head, she said, was not quite right, and she was troubled with some dizziness; she felt weak in the legs, and had feelings as of ants crawling between the skin and flesh of the lower limbs. She remained pretty much in that condition, one day feeling badly and the other better, for about six months, when she was forced to relinquish work and went to consult a physician, who treated her several weeks for dyspepsia, but with no relief. She became almost bedridden at that time, and, after changing several medical advisers, sent for me in December, 1884. I found the patient in nearly the condition described, though very much weaker and considerably emaciated; she remained altogether indoors, getting up from bed two or three times during the day, and only for a few minutes at a time. She felt well only while in the supine posture; her only nourishment consisted of two or three cupfuls of milk and weak beef-tea. I had no difficulty in immediately recognizing in her affection spinal irritation. I prescribed first a little whiskey and milk-punch at frequent intervals, day and night; this she retained with comfort. I then ordered a more generous diet, and gave internally one-sixtieth grain of strychnine three times a day, progressively increasing the dose, and the compound syrup of hypophosphites; I also began electrical applications, using the galvanic battery, and applied ascending and descending currents to the spine for from five to ten minutes every day. In a month's time the patient was so much benefited that she was able to come to my office, and in a few weeks more I discharged her cured. I meet this patient at frequent intervals, and she has had no return of her affection.

Case II.—In the summer of 1883 I was called in consultation by Dr. Bemiss, to see one of his patients in Ward 18 of the Charity Hospital. A. R——, aged nineteen, white, male, born in New Orleans, had had malarial fever of an intermittent type for some weeks. When examined he had been free from fever for some days, but he complained of exquisite pain on pressure over the lower dorsal vertebræ, with great weakness, pain, and numbness in the lower extremities; he felt comparatively at ease when lying down, but could scarcely stand on his legs; he had no gastric trouble, but had some difficulty in voiding his urine and was costive.

The case was pronounced one of spinal irritation, and the patient, being put on progressively increasing doses of sulphate of strychnine, with a generous diet and free stimulation, made a rapid recovery.

In searching over the patient's history no tendency to neurotic affections could be detected, and the malarial fever was evidently the sole cause of the spinal irritation in his case.

Case III.—M. B——, white, female, aged twenty-six, who has had one child, is highly nervous, but has never had any hysterical attack; gives a history of spinal irritation affecting the upper dorsal region four years ago, lasting several months, and being followed by complete recovery. She was admitted to Charity Hospital medical service in the early part of 1886, where she remained several months; she was then transferred to the gynecological ward, and was operated on for lacerated cervix uteri with success, but with no improvement in her general condition. In October, 1886, she was transferred to my service, presenting the following symptoms: Great tenderness over the lumbar spine, great pain and tenderness in the lower part of the abdomen and the lower extremities, inability to stand from weakness of the legs, retention of urine of several months' duration from spasm of the sphincter of the bladder, amenorrhœa of four months' standing, and costiveness. The muscles of the paralyzed parts were stiffened but well nourished, and responded normally to irritation. Treatment for spinal irritation. The patient was discharged, cured, two months after admission.

Diagnosis.—Spinal irritation, when fully developed, with all its regular complex of symptoms, is not difficult to recognize. In forming a diagnosis the principal points

to be relied on are: The presence of pain in the back, developed or increased by pressure over the whole or part of the spine; excentric symptoms, affecting chiefly sensibility, but to a slighter extent the motility also, of parts of the body receiving their nerve-supply from the affected portion of the cord, and various visceral disturbances already mentioned; the changeable character of the symptoms and the fluctuations in the course of the disease; and finally, the want of proportion between the severity of the subjective and the mildness of the objective symptoms.

The diseases with which it is more likely to be confounded are: The earlier stage of myelitis and spinal meningitis; spinal hyperæmia, hysteria, and spinal neurasthenia.

In myelitis we have absence of hyperæsthesia and tenderness, except on deep pressure over the spine; severe paralysis of sensation and motion in the extremities, and complete visceral paralysis; painful contractures and spasms, the absence of the nervous condition found in spinal irritation, and generally a fatal termination.

Meningitis spinalis is more difficult of differentiation; stiffness and painful contraction of the muscles of the back, pain in the spine, increased by motion, but not affected by pressure, with absence of tenderness in the part, the presence of fever, late paralysis, etc., will, as a rule, however, be sufficient to enable us to establish the diagnosis of meningitis.

Hyperæmia of the cord is still more difficult to distinguish from spinal irritation; indeed, some authors claim, as stated above, that the symptoms of the latter disease are due to a congested condition of the spinal marrow. The general absence of tenderness or pain in the spinal region, and the fact that the symptoms are aggravated by the recumbent position on the back, are characteristics of importance in spinal hyperæmia, and will generally suffice to distinguish it from irritation.

Hammond proposes as a test between these affections the relief given in hyperæmia and organic spinal diseases by the administration of ergot, while spinal irritation is made worse by the drug; and, on the other hand, the marked improvement in the symptoms of the latter affection caused by the use of strychnine, and the aggravation of spinal hyperæmia and the other diseases by the exhibition of this drug.

The characteristic globus, general spasms, and other symptoms of hysteria will suffice to establish a diagnosis between this affection and spinal irritation, though it must be remembered that the two are frequently found associated.

Neurasthenia spinalis, though resembling the disease under consideration, will be recognized by the fact that it is usually found in the male sex, by the absence of extreme spinal tenderness, and by the general preponderance of motor symptoms over those referring to sensibility. The two diseases have, however, an undeniable general resemblance.

Angular curvature of the spine from vertebral caries is not likely to be confounded with spinal irritation, and its characteristic symptoms need not be referred to here.

PROGNOSIS.—The prognosis is in general favorable, the majority of cases being cured, and a large number of the others benefited by judicious treatment. In a minority of cases improvement is, however, very slow, and at times imperceptible, and in others relapses are very frequent. Death has never been known to be caused by this affection, but some of the patients are doomed to a tedious illness, lasting perhaps for years.

TREATMENT.—The main treatment in spinal irritation should be directed to the removal of the cause of the affection, and to the improvement of the tone of the general nervous system and of the spinal cord in particular. It will suffice for us to refer our readers to the causes already mentioned to see how best they may be removed. To obtain the second object, hygienic and medicinal means are to be employed, such as a generous diet with plenty of wine and other stimulants, passive and active exercise for short intervals in the open air, the keeping of the recumbent posture for the greater part of the time, etc. The judicious use of certain drugs presently to be mentioned, and of electricity, is also necessary.

Cupping and blood-letting are scarcely ever indicated; counter-irritation to the spine by means of blisters, tartar-emetic ointment, or iodine, is of great use; hot applications to the back, or the use of the ascending galvanic currents with the two poles on the spine, one above and the other below the tender part, are recommended by Hammond as of great service in diminishing the tenderness.

Of the drugs themselves strychnine, in progressively increasing doses, is very useful; the phosphide of zinc in one-tenth grain doses three times a day, phosphorus, and phosphoric acid, are also of service. Opium, the bromides, and chloral are sometimes indicated, and general faradization with central galvanization is also recommended. Mountain- and forest-air is to be advised. Cold-water baths have proved beneficial in some cases.

SPINAL CORD DISEASES: TABES SPINALIS. This term is applied rather vaguely to all forms of spinal disease attended by slow wasting of the substance of the cord, but of the posterior column especially. I think it is better than "locomotor ataxia," which is the term in popular use, or "tabes dorsalis," which just now it is the fashion to apply to cases of locomotor ataxia when there are only a few or no motor disorders. "Locomotor ataxia" is simply a clinical appellation, and its symptoms are not necessarily due to posterior column disturbances, but to lemniscal lesions, alcoholic neuritis, or other conditions. There is still a condition which is denominated "ataxic paraplegia," which is, after all, a hybrid disease. Tabes spinalis may be said to be an affection confined for the most part to the posterior column of the spinal cord, and attended by abolition or impairment of centripetal transmission and the irritation of the posterior nerve-roots, with varying sensory derangements, abased or increased tendinous reflex activity, motor inco-ordination, optic-nerve atrophy, and frequently various evidences of derangements of the sympathetic nervous system.

Although Todd directed attention to a variety of symptoms which are now recognized as those of the disorder, it is to Romberg[1] that the credit belongs of first accurately describing the disease under the name of *tabes dorsalis*, and who presented an autopsy made by Froriep in which degeneration of the posterior parts of the cord was found. In 1868–73, Duchenne de Boulogne revived interest in the subject by an elaborate and advanced consideration of the subject, and about the same time Trousseau, Charcot, Pierret, and other writers in France, and Westphal in Germany, added much to the literature, especially of the morbid anatomy. In Charcot's early work he established the existence of trophic changes, both osseous and dermal, and very little has been since added to his description of the arthropathies.

In England Russel Reynolds was among the first to consider locomotor ataxia, objecting to the prefix "progressive," which had been applied by Duchenne, and latterly Buzzard and Gowers have written well and extensively. In 1870–75 American writers, including Hammond, Clymer, Seguin, and myself, described the affection and presented cases.

The disease is one of a chronic and progressive nature, and while there are rare exceptions to this rule—especially those of traumatic causation—the greater number run a prolonged course marked by three stages: 1, The

prodromal, or *pre-ataxic* of some authors ; 2, the *developed*, or *ataxic* ; 3, the *degenerative*, or *stage of decline*. There are irregular varieties, one of which is known as the *hereditary*, or family, in which the subjects are young children, and there is a family history ; and Obersteiner and others have considered an ascending form which eventually has a cerebral extension, and is expressed by symptoms of mental disorder. There is also a form described by Fournier as *sclérose cérébro-spinale postérieure*, which is so irregular as to lead me to divide all cases of the disease into the *syphilitic* and *non-syphilitic*, the former, as it will be seen later on, being largely in the majority.

ETIOLOGY.—It was the generally entertained belief, until within a few years, that locomotor ataxia was due in nearly all instances to sexual excesses, an impression which probably grew out of the fact that most of these patients were syphilitic, and many syphilitic patients were amorous free lances. The real nature of the syphilitic causation was lost sight of until ten or twelve years ago, when Erb and others brought forward most astonishing statistics. The conclusions of the first author are very extreme, and he holds that ninety per cent. of all patients have a history of specific disease. In Germany and elsewhere he has many supporters, but there are a few men of temperate diagnostic zeal who reduce the proportion of syphilitic cases. Seguin has been unable to find more than twenty per cent.*

My own experience leads me to the conclusion that there are two classes of cases which possess some common characteristics, but which are very dissimilar in some ways. In one of these syphilis plays an active part, in the other there is no veritable specific history ascertainable. If we group these cases together a very high percentage of syphilitic cases is to be found, but the ratio of the hybrid cases,† in which syphilis is undisputed, is great to those of regular type and conventional progress. Of this class it is probable that fully ninety per cent. are syphilitic. Of what may be called the fixed-type class, there is not more than twenty per cent., or even less, where a reliable history of syphilis is to be found.

LOCOMOTOR ATAXIA OF IRREGULAR TYPE (SYPHILITIC).	LOCOMOTOR ATAXIA OF REGULAR TYPE (RARELY SYPHILITIC).
Of rapid progress ; prodromal stage short ; ocular symptoms early and diversified ; tendon reflex usually returns and is exaggerated, or is exaggerated from injury ; mental symptoms marked ; optic neuritis ; choked disk ; ataxia irregular ; possible extension to "general paresis ;" anæsthesia often irregular. Arthropathies uncommon. The young subjects with local cranial paralysis complicated with ataxic symptoms are usually syphilitic.	Of slow progress ; first stage often long—ten or twelve years ; Argyle - Robertson symptom ; pains and absent reflexes almost only early ocular symptom ; slow white atrophy ; ataxia of slow origin and bilateral ; plantar anæsthesia usually well distributed ; mental defects rare ; arthropathies common. Rarely helped by iodide of potassium.

Buzzard calls attention to the error one may fall into by impulsively choosing syphilis as a cause, when the pains and early symptoms may have preceded the syphilis for some years. I have borne this in mind in the examination of every case, and can support his views most emphatically. So far as sexual excesses go, I believe that any method of cohabitation which implies repeated spinal shock and exhaustion, must invite the approach of disease, and it is probable that forced and frequent connection, especially when the pleasures of Bacchus and Venus are enjoyed simultaneously, may sometimes originate a spinal exhaustion which will soon terminate in sclerosis ; but this is rare. The exceedingly fanciful ideas in regard to these causes entertained by the Germans are sometimes very laughable and improbable, and one writer in Ziemssen gravely alludes to the perils of coition in the erect posture, while another finds that twelve of his cases were addicted to the habit of *coitus reservatus*, a method which in this country, I believe, is common only in the Oneida community.

Sudden exposure to damp and cold, for which the person is unprepared, is quite likely to cause the disease. As instances I may mention patients who fell overboard or who stood in wet places while shooting. One patient left his warm bed and descended into his yard to chase burglars, without taking the precaution of putting on shoes or slippers. Traumatic cases of the malady are by no means unusual, though the exact manner in which injury gives rise to the disease is a matter of doubt. In making this assertion I leave out of question the cases of actual local vertebral violence, and the production of spinal bone lesions, and possibly meningitis confined chiefly to the posterior part of the cord. Railway concussion has resulted in a manifestation of symptoms indicative of locomotor ataxia. It is not of these cases I speak, however, for the morbid expressions are usually diverse. The traumatic scleroses are those, strange to say, where the rapid appearance of symptoms of posterior column disturbance has followed fracture of one of the long bones. I have seen several such cases.

Hereditary cases are of a distinct type, and I am convinced are not purely localizable posterior sclerosis. I feel sure that the real cause of such congenital disease is often a syringo- or hydro-myelia, the cavity occupying the posterior half of the cord.

Tabes is rarely found in women, and I can recall but a dozen personal cases of several hundred I have seen during the past twenty years, and four of these were syphilitic subjects. But two of these patients were classical cases, and the symptoms were due to lesions limited to the posterior root-zones of the spinal cord. Of Eulenberg's 149 cases, 128 were males and 21 females. The experience of other authors is my own. As to age we find that, except in rare instances, the disease seldom attacks individuals under twenty. Leyden fixes the limit as between the twenty-fifth to forty-fifth years.

Of Eulenberg's cases, to which allusion has just been made, the ages of invasion were :

	Male.	Female.
Below 10	0	1
10 to 20	2	0
20 to 30	35	12
30 to 40	39	7
40 to 50	47	1
50 to 60	5	0
Over 60	0	0

SYMPTOMS.—The prodromal symptoms of tabes are vague and irregular, but, like the early indications of so many serious nervous diseases, are mostly sensory. For a long time the early advances of the malady may be disregarded by the patient or his friends, and the pain ascribed to several causes. Many ataxics are regarded in the beginning as hypochondriacs, even by competent medical men, and sometimes a careful examination will fail to reveal anything positive ; for while the two earliest positive indications—the Argyle-Robertson pupil and the absent tendon reflex—are to be determined in the majority of cases at a time when nothing else is manifested, there are many exceptional cases where the ocular symptom is not present, and where it is possible to evoke a patellar tendinous reflex by proper excitation. In the ordinary cases the patient complains at a very early period of fatigue and uneasiness in the lower extremities, and some persons have likened the sense of tingling and fatigue to that which follows a long walk. The muscles at the back of the thighs and legs are tired and sore, and the ankles and knees are "weak" and ache. Slight exertion produces discomfort, and after a while actual pain of a shifting character and some plantar formication. Mental feebleness is also manifested, sometimes the patient being depressed or peevish, and hypochondriacal. He is annoyed, morbidly conscious of the attitude of his friends, and fearful of some impending disaster. Appetite and flesh are often reduced, and the bowels become sluggish. Some of my patients have complained of headaches, and these have been dull, lasting for several hours, and with subsidence there has been a free action of the kidneys, with the elimination of a large quantity of clear urine. The vision is more or less impaired, and

* Buzzard, while admitting that his notes are imperfect, found that 25 of 53 cases had a syphilitic history. Of Fournier and Erb's 127 cases, 59.8 per cent. were syphilitic. The average percentage of five American authors was 41.4.

† Many of them cases of ataxic paraplegia.

Spinal Cord.

transient attacks of diplopia are annoying. The pupil undergoes a change in its susceptibility to light stimulation, which has been described by Argyle-Robertson. This consists in preservation of the ability of the eye to accommodate with, of course, normal contraction or dilatation, but a failure of pupillary response to light stimulation; and it has been found that, owing to the abolition of the skin pupillary reflex, no dilatation of the pupil follows the pinching of the neck, which is the case in the normal individual. This symptom is by no means constant, but is a very common and suggestive indication.

In many cases we find even the pre-ataxic stage of the malady marked by disappearance of the patellar tendon reflex. The absence of the *knee-jerk*, which was first described by Westphal, may be determined best by making the patient sit upon a high table or desk, so that his thighs are well supported and his legs hang loosely at right angles. Then a smart blow may be struck with a ruler or small percussion hammer just below the patella, or to one side over the fibular head. No movement of extension may follow, though a light tap over the vastus externus may evoke a well-marked contraction. The loss of the reflex may be unequal, that is, it may be present on one side and absent on the other. The other reflexes of the lower extremities are apt to be lost or diminished. Mitchell and a host of other observers have shown that the tendon reflex varies under different conditions. According to the latter, the action of the will in some other direction is apt to increase or conserve an apparently dormant reflex. This I have not been able to verify. This bluntness of the reflex is quite apt to be found in other places, and the reflex functions of the bladder are deranged, with a resulting difficulty in voiding urine.

Brissaud has devised a remarkably ingenious apparatus, by which the force of the knee-jerk may be exactly measured. In some cases, even at a very early stage, the tendinous reflex will be increased.

The Established Disease.—After a variable siege of premonitory symptoms we come to the pre-ataxic stage, which is often of long duration, and is characterized by the advent of pain, the loss of the tendinous reflex, the occurrence of pupillary changes. The pains of the ataxic are peculiar and almost unique. They are paroxysmal, fugitive, and intense—and, like those of the uncomplicated neuralgiæ, are greatly aggravated by change of barometric pressure. I have kept the records of one patient for several years, and in his case every easterly or southwesterly wind was preceded by an exacerbation of leg pain, which was as certain as the barometer. The pains more often have their seat in the thighs—usually the inner surface—but the tract of the great sciatic may be the chosen spot. With great suddenness a twinge of the most intense description will affect a spot not much larger than a quarter. Light at first, it increases in gravity, and, after a few minutes or a few hours, subsides and attacks some other spot. The quality of the pain has been likened to the tearing of flesh, the introduction of red-hot needles, and to various methods of torture—and the names *terebrating, needle, boring, stabbing*, have been applied, and *fulgurating, lightning*, with regard to their suddenness and violence. Sometimes the ankles or soles of the feet may be the seat of the painful spots, and I have often found the popliteal space to be the locality. In some cases the pains dart up and down the course of a nerve. There is a second variety, which is dull and in some respects resembles rheumatism; with this there is pain on movement, and considerable interparoxysmal soreness. The pains of posterior spinal sclerosis are by no means regular in their expression, for the patient may have them on one side or on both, and with varying degrees of severity. Subjective coldness of the limbs is common, and with the pain there is often cramping of the toes, and clonic contractures of the lower extremities, which is semi-involuntary. The patient does not seem to be free from suffering at any time that may be counted upon. The suffering is perhaps more extreme at night and more constant. In some cases the ataxic pains choose sites which are peculiar—the lightning pain attacking parts about the anus or running up the rectum, and with this there is a sense of perineal weight and some tenesmus. Testicular pains are rare, but are sometimes found, nevertheless, and clinicians have called attention to a horrible form of misery which consists in vaginal and vulvar pains, which are present in sclerosis in women—which is rare.

After a variable siege of pain lasting from a few months to even twenty years, we find other sensory manifestations, such as anæsthesia, hyperæsthesia, and paræsthesia, delayed conduction of sensation, and a loss of the muscular sense. As the disease is more often in the lumbar part of the cord than elsewhere, we naturally find most of the trouble below the waist. The anæsthesia may be uneven at first, and afterward general, or, if there be ascending degeneration, the fingers, hands, and arms are involved. A rare locality in cases in which the tabes invades the upper part of the cord is the episternal. In a few cases I have found a circumscribed area of anæsthetic skin in this situation. The common form is that known as "plantar," and much of the patient's unsteadiness is due to his inability to preserve his sense of contact. When his eyes are closed he readily falls, or when he washes his face he is apt to pitch forward. At night it is impossible to walk about the room without support of some kind. This anæsthesia of the soles may be unequal, so that perverted impressions are received. A feeling as if foreign bodies were in the shoes is a familiar complaint. Sometimes the sensation is compared by the patient to that which might be produced by sand or wool beneath the feet; again, as if the stocking was down at heel. A more grave, and correspondingly rare, form of anæsthesia is that of the vagina or rectum, and if the upper tracts be involved we find occasionally a faucial and buccal anæsthesia; but these phenomena do not belong to true cases of tabes spinalis.

Tactile sensation is decidedly blunted, and the perception of painful contact as well. Various experiments have been undertaken to determine the time of transmission of a pin thrust, for instance, in the lower extremities. In some cases the delay in perception is equal to a quarter of a minute. We may find that the painful impression is transferred and felt on the opposite side (allochryia), a curiosity described by Hammond; or it may be perceived several times after one irritation. In fact, all sorts of sensory anomalies are presented. The patient loses his ability to appreciate weight, and is unable to make comparisons.

In some cases the "constricting-band" symptom is presented, which, however, is more common in acute myelitis than in the disease under consideration. This girdle sensation, or paræsthesia, is often found at the same time with vesical atony. The superficial reflexes are exaggerated until the plantar anæsthesia is complete, though the knee-jerk be absent.

In the established disease the pains in the lower extremities are not those alone which annoy the patient. Intense, lancinating pains, called by the French *crises gastralgiques*, invade the trunk and much torture results. The pain is colicky, but much more violent than the familiar condition of suffering, and is fugitive. Sometimes it is attended by diarrhœa and by bloody discharges from the lower bowels, as well as vomiting. Cardiac pains like those of angina pectoris are features of tabes, but rare. In some examples of the disease the gastric crises take the place of the fulgurating pains in the lower extremities, and are a feature of the second stage; but in many cases the distal pains occur from time to time in the well-established malady.

As the central process of disease is confined chiefly to the dorsal and lumbar region of the cord, we find corresponding motor disturbances chiefly of the lower extremities. The patient begins to grow clumsy and awkward, not from a loss of power, but from an impaired ability to grasp the amount of muscular force he desires to use. When he stands with his feet approximated laterally, he sways to and fro, and often has to extend his arm, as a rope-walker would, to preserve his balance. When he walks there is rigidity, especially when descending a staircase or crossing a street, when he is in danger

of being run over. He comes down upon his heels, and these will be found worn. He spreads his feet, and the gait is swaying, the soles being "brought down with a slap," which gives his propulsion an appearance never to be mistaken. When he attempts to turn there is much tottering, and when he is embarrassed he is sometimes almost helpless. If the disease advances beyond this, defective co-ordination is seen when he attempts to perform acts requiring delicacy of adjustment—such as buttoning his clothing, winding his watch, writing, or using small instruments of any kind. He is unable to localize small spots.

The ocular symptoms of tabes are numerous. I have already alluded to the pupillary derangements, and, *en passant*, to the atrophy. There may be paralysis of the third nerve, usually single, but occasionally double. (See Charcot's case.) In fact, any of the muscles of the ball may be paralyzed, or all of them, giving rise to *ophthalmoplegia externa*.

A slow atrophy beginning in the early stage of the disease is a frequent symptom, and with it we find color-blindness and limitation of the field of vision. In one case of my own, a woman, there is very slight ataxia, absent reflex, light pains, a gradual loss of vision, and intense headache. In fact, this headache is very common with the neuritis of tabes.

The sexual organs undergo changes which consist usually of a tendency to priapism, nocturnal emission, and other evidences of irritability in the beginning, and a complete loss of power later on. The action of the bladder is impaired and the urine is passed slowly, and often falls with but little force from the end of the penis. It often contains a large quantity of the earthy phosphates or epithelial *débris*, and decomposes rapidly.

When the ataxic stage has existed for some time, the sympathetic nervous system seems to participate in the production of symptoms, and a variety of trophic changes occur which have elsewhere been described. (See Arthropathies.) Articular destruction, with luxation resulting from absorption of the heads of the long bones, especially of the lower extremities, is common. The alveolar processes undergo a change, so that the teeth become loose and drop out even when they are sound.

Various skin disorders, among them herpes and pemphigus, are found in old cases, and there may be dermal roughening or thickening. The nails, too, become affected, as Charcot has pointed out, and even exfoliation occurs. One evidence of a sympathetic complication in tabes is the acceleration of the pulse, which is permanent.

A grave trophic degeneration is that known as *perforating ulcer*, and is peculiar to tabes. Luckily it is a rare feature. An indolent ulcer forms usually upon the sole of the foot, which may lead to the necessity of amputation.

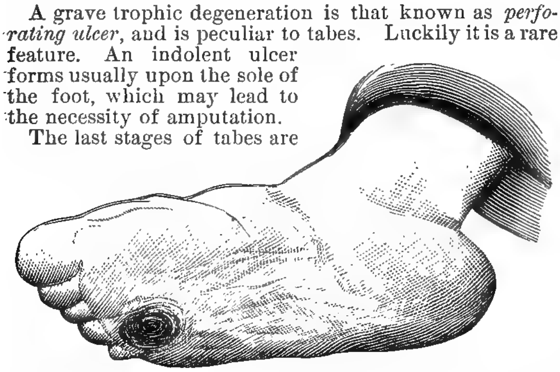

FIG. 3654.—Perforating Ulcer of the Foot in Tabes. (Gowers.)

The last stages of tabes are those attended by complete helplessness. The motor difficulties increase, the patient becomes thin and feeble, and the possible existence of repeated gastric crises, with vomiting and diarrhœa, leads to great exhaustion. Tuberculosis is not a rare result of such malnutrition. In some cases the arthropathies cripple the patient to such an extent that he passes the last years of his life in bed.

MORBID ANATOMY.—When the spinal cord is removed and examined, it is possible to find some external pinkish-gray discoloration at its posterior part. When a transverse section is made, this same opalescent appearance is detected. It is uneven both as to extent and situation, but more uniformly present in the lumbar region than elsewhere, though plaques of sclerosis are often found at higher levels or in the trunks of nerves. The finger passed over the posterior surface of the cord often reveals an induration. When a transverse section is made, discoloration may be detected by the naked eye between the two posterior cornua, which is somewhat translucent.

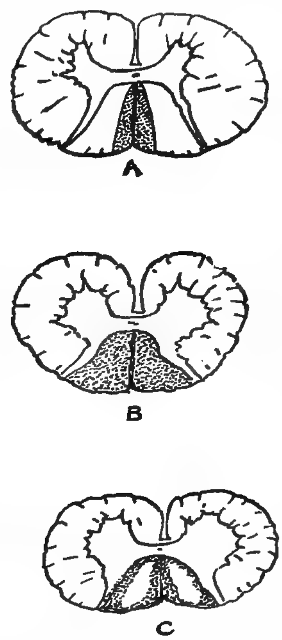

FIG. 3655.—Diagrammatic Representation of Common Areas of Sclerosis. A, Sclerosis of postero-median columns (Goll's column), most distinct in cervical region. B, Sclerosis of entire posterior columns. C, Sclerosis of parts of postero-median and postero-external columns, leaving central parts exempt.

The microscope reveals characteristic appearances in the lumbar, dorsal, and cervical portions of the cord, and the extent of the sclerosis depends largely upon the duration of the disease. We may find that the entire tract included by the commissure in front, the external roots laterally, and the posterior boundary of the cord, is the seat of a dense hardening, or we may appreciate various degrees of transformation. The most constant appearance, when the morbid process can be recognized at all, is adjacent to the posterior cornua, and next the column of Goll or postero-median columns. In ascending degeneration we find in the cervical and dorsal regions a density of tension in these columns, even when there is a more complete increase of neuroglia below; while the postero-external columns are longer exempt from involvement. The gravity of alteration is usually at first seen quite posteriorly, and even after extension the fibres of connective tissue radiating from the periphery are thicker than elsewhere. In some cases we find a tract of healthy tissue surrounded by a territory of sclerosis. In this form of sclerosis, as in others, the nerve-elements are more or less destroyed and their places are filled by thickened trabeculæ containing nuclei. The vessels found have thickened walls, and the outer coats are especially the seat of degeneration. Broken-down elements, amylaceous corpuscles, and the like are seen.

Numerous associated changes are often present—such as atrophy of the spinal nerves, meningeal thickening, and extensions of the morbid process into the lateral columns, and even the gray matter, are found. It is rare for any disappearance of the large nerve-cells of the anterior horns to take place, unless there is an associated atrophic condition. Sclerosis of the cranial nerves, or of the pons and posterior cerebral ganglia, are found in a small number of cases.

DIAGNOSIS.—Tabes spinalis is apt to be confounded with disease of the pons, alcoholic neuritis, cerebellar disease, cerebro-spinal sclerosis, and certain hysterical affections. In the early stages the pains are apt to be mistaken for those of rheumatism or neuralgia, but the peculiar nature of the symptoms—the non-involvement of the articulations and the association of the lost knee-jerk—are guides which should not be disregarded, and the same may be said of the Argyle-Robertson symptom. In some cases of disease of the pons there is inco-ordination, but the other associated symptoms—especially the pupillary contraction and absence of lightning pains—are suggestive. Alcoholic neuritis occasionally gives rise to

inco-ordination and ataxia. The pains in the lower extremities are, however, nearly always present, and there is tenderness of the plantar surfaces, glossy skin, and ordinarily atrophy. In many cases there is noticeable mental weakness. In cerebellar disease there is reeling and vertigo, and the walk is rather that of a drunken man. There is nystagmus, double neuritis, headache, and vomiting, none of which symptoms are ordinarily found in tabes. The tremor of cerebro-spinal sclerosis is not found in tabes; the mental dulness of the former is characteristic, and the speech disturbance is unknown in the spinal affection. The pains of tabes are never found in any of the forms of coarse disease I have mentioned.

PROGNOSIS.—Tabes spinalis is a progressive and fatal affection, and I do not know of a well-authenticated cure. In making this statement I exclude the syphilitic cases, but these even are only rarely cured by any treatment. The duration of the disease is exceedingly variable, and may extend from a few months to twenty years or more. The traumatic and some syphilitic cases are rapid in their development and unfavorable progress. The course of the disease is marked by periods of temporary improvement, and is retarded by proper therapeutical measures. I have effected an apparent improvement, in some cases, which has lasted several years, but the symptoms returned and the disease advanced. Optic-nerve atrophy is an exceedingly bad feature, and the development of the second or ataxic stage is an almost positive sign of a hopeless prognosis. Of the reported cures, doubtless these include examples of ataxia due to alcoholic neuritis, hysteria, or plantar anæsthesia of limited duration.

TREATMENT.—In specific cases our main reliance must rest upon heroic doses of the iodide of potassium—even several hundred grains daily may be given if the patient can bear such a quantity. The use of alkaline waters as a vehicle will enable him to take a much larger dose without gastric derangement than if water or other menstruums are used. Nitrate of silver and the tribasic phosphate sometimes improve the patient's condition, but arsenic is one of the best agents, and Gowers speaks highly of its efficacy in his hands. There is nothing, I am convinced, so important, not only in tabes, but all other forms of sclerosis, as *rest.* When this is possible we may greatly relieve, if not permanently improve, the patient, and a lady who consulted me after the development of the second stage, and who took to her bed and remained there for six months, has had very little trouble for several years, her gait being almost unaffected, and her pains entirely absent. I have known of very decided relief afforded in other cases by enforced rest. The gastric crises and occasional diarrhœa are best helped by morphine, and at such times rest is more important than at any other. Cod-liver oil and the hypophosphites are especially serviceable in the third stage.

The pains of the first stage are very difficult to relieve, except by morphine, which, strange to say, is usually well borne, and I have never seen the formation of the habit but twice. Sometimes the cases are helped by the salicylate of soda, antipyrin, or acetanilide (antifebrin), the latter by the mouth or subcutaneously. Various authors recommend the local application of chloroform, the tincture of aconite, or bisulphide of carbon by means of pledgets of cotton in wide-mouthed bottles. Cod-liver oil and the fats are necessary, and the discontinuance of tobacco, alcohol, except in an easily assimilable form, sexual intercourse, and exposure to extremes, is imperative. A warm winter climate should be selected—one of low elevation and withal dry is better than any other; and if it is possible to go to some sulphur bath, such as Sharon or Richfield, or the springs of Virginia in this country, or Aix-la-Chapelle, or those in the south of France, the patient will doubtless obtain much benefit. I would advise Southern California or Thomasville, Ga., or, in fact, any inland warm place. The Florida seacoast is not recommended, but such pine districts as that in the neighborhood of Seville, Fla., are suggested. I will say nothing about a variety of agents for the relief of special symptoms, vesical or trophic, for remedies will suggest themselves; but the physician is urged to carefully attend to the many little disturbances that may without care attain a dangerous magnitude.

It will be found that the patient's comfort can be greatly increased by the use of leaden insoles which are heaviest in front. *Allan McLane Hamilton.*

SPINAL CORD DISEASES: TOXIC SPINAL PARALYSIS. Paralysis may be caused by various toxic agents, among the more important of which are lead, alcohol, arsenic, phosphorus, mercury, carbonic oxide, carbon sulphide, tobacco, camphor, ergot, and copaiba. The paralysis may occur in hemiplegic or paraplegic form, or may attack only groups of muscles, but in most instances its exact character has not been definitely determined.

The toxic paralysis most carefully studied is that due to lead-poisoning. It is most commonly found in the form of wristdrop—paralysis of the extensors of the fingers and wrists—but lead may cause far more extensive paralysis. Post-mortem examinations in such cases have revealed extensive degeneration of both muscles and nerves, and in a number of instances disease of the anterior cornua of the cord. The view now most commonly accepted is that the disease is primarily an anterior poliomyelitis—inflammation of the gray matter of the cord—and that the pathological changes in the muscles and nerves are secondary effects. Lead-paralysis would then be a spinal paralysis. But many still believe that it is mainly a peripheral paralysis, primarily in the nerves and muscles. Their opinion is based upon the extensive disease in the latter, and the ofttimes negative results of examination of the cord. The question cannot be considered as definitely answered.

One of the most common, if not most common, forms of toxic paralysis is that due to alcohol. Most post-mortem examinations of such cases in recent years have revealed the presence of multiple neuritis, with, in some instances, inflammatory changes in the cord at the same time. Alcohol-paralysis seems, then, in greater part to be a peripheral paralysis, due to neuritis.

Arsenical paralysis, especially in its clinical aspects, has been carefully studied in recent years. It sometimes has the appearance of peripheral paralysis, sometimes occurs in paraplegic form, and occasionally simulates locomotor ataxia, with ataxic gait, absence of patellar tendon reflexes, etc. It is not improbable that most of these paralyses are also due to neuritis. The same pathological basis may exist in the other forms of toxic paralysis, which have been less carefully studied. We may therefore be permitted to discontinue the discussion of the subject in this article, which is to treat only of spinal paralysis, particularly as it requires much further elucidation before anything can be stated definitely. But it is not improbable that toxic agents produce paralysis sometimes through the central nervous system, brain, or spinal cord, sometimes through the nerves; and the question is yet to be answered to what extent neuritis, especially multiple neuritis, so much spoken of recently, is due to conditions of the central nervous system.

Philip Zenner.

SPINAL CORD DISEASES: TUMORS OF THE CORD AND ITS MEMBRANES. Tumors within the vertebral canal, whether they spring from the cord itself or the meninges, produce symptoms mainly through irritation or destruction of nervous tissues. As they can rarely, if ever, be differentiated during life, it is convenient to treat of tumors of the cord and of the membranes at the same time.

The larger number of intraspinal tumors grow from the membranes, from the dura mater more frequently than from the pia mater; a smaller number originate in the cord, either in its substance or in the peri-ependymal tissue around the central canal. Some intraspinal growths spring from the bone or intervertebral substances, others from the tissues outside the vertebræ,

entering the canal through the intervertebral foramina. Circumscribed inflammatory exudations, from caries of the vertebræ, and hæmatoma, as they may produce similar manifestations, are sometimes included among intraspinal tumors.

The most common forms of tumors springing from the membranes are fibroma, sarcoma, and gumma; from the cord itself, glioma and tubercle. Among the tumors less frequently found in the cord or its membranes may be mentioned psammoma, lipoma, myxoma; tumors of a mixed type, myxo-sarcoma, glio-sarcoma; and parasitic growths, echinococcus, more rarely cysticercus. Neuromata, especially false neuromata, are found on the spinal roots, sometimes in large numbers. Enchondromata, sarcomata, and cancerous tumors sometimes spring from the bones or intervertebral tissues and compress the cord. Primary carcinoma is scarcely, or not at all, found in the cord or its membranes, but secondary deposits, especially after primary disease of the breast, are not very rare.

Tumors are most frequently single, but neuromata on the spinal roots are often multiple, and tubercles in the cord, though usually solitary, may occur in larger number, while secondary carcinomatous deposits are, perhaps, usually multiple.

The shape of intraspinal tumors is usually round, oval, or elongated. Their size is necessarily very limited, varying from that of a hemp-seed to the diameter of an inch or more. Tumors in the dura mater are usually larger than those in the pia mater. In the cord they rarely exceed one-half inch in transverse diameter, but sometimes have quite a considerable vertical extent, in some instances of glioma and myxo-glioma reaching the whole length of the cord.

Tumors may be found anteriorly, posteriorly, or laterally in the membranes, and therefore encroaching upon the cord, sometimes in one direction, sometimes in another. They may also be found in any part of the vertical extent of the cord or membranes, though tubercles are said to occur most frequently in the lumbar enlargement, and gliomata in the cervical region of the cord.

The tumors are usually distinctly circumscribed; sometimes—this is especially true of gliomata—they blend with the cord-substance.

The secondary changes in the nervous structure, produced by the compression or destructive action of the tumor, are of the greatest importance in the production of symptoms. Tumors growing from the membranes usually produce decided inflammatory or atrophic changes in the spinal roots and cord. The spinal roots are usually swollen and red, or in a state of inflammatory softening; in other instances they are degenerated and atrophied. Compression of the cord causes it to be flattened or narrowed at the point of pressure; sometimes produces an entire solution of continuity at that point, the extremities of the upper and lower segments being connected together by membranous tissue. The pathological changes in the cord-substance are sometimes only atrophy of the nervous elements, but usually there is a secondary myelitis, termed compression-myelitis. The cord is in a condition of white or red softening, with small extravasations of blood in the softened area, the microscope revealing granular cells and fragments of nervous elements. The inflammatory process is likely to extend some distance below the seat of compression, especially in the gray matter; and occasionally it extends a short distance above the point of compression. Degeneration of the white columns of the cord above and below the lesion, according to the Wallerian law of secondary degenerations, is usually found. A localized chronic meningitis in the neighborhood of the tumor, often resulting in an increase of fluid within the vertebral canal, is frequently present.

Tumors in the substance of the cord compress and push apart the component parts. They may merely produce atrophy of the neighboring tissues, but generally cause more or less inflammation. Often they produce transverse myelitis, with all its symptoms. Secondary degeneration takes place just as after other considerable lesions of the cord. The tumor may also produce a localized meningitis and morbid changes in the spinal roots.

Various secondary changes also take place within the tumors themselves, such as softening and formation of cavities. Some cases of syringomyelia—cavities in the centre of the cord—a very interesting pathological condition, though of little practical importance, as it usually produces no symptoms, are merely secondary cavities in the middle of a tumor. Hæmorrhages sometimes occur within the tumor or in the surrounding tissues. This is most likely to take place in those rich in blood-vessels—angio-gliomata and angio-sarcomata.

The secondary changes in the spinal roots and cord just described, and the symptoms induced by them, are produced to a variable degree by different tumors. These effects depend upon various factors, of which the most important are location, size, consistency, rapidity of growth, and tendency to destroy neighboring tissues. The last two qualities are especially important. Rapidly growing tumors produce great irritation, and have a special tendency to produce inflammatory changes. On the other hand, psammoma, a hard but slow-growing tumor, is slow to produce symptoms. Those tumors which have a tendency to destroy surrounding tissues—tubercles, to some extent gummata, but especially carcinomata—produce very intense symptoms. Consistency is also important. Tumors softer than the cord may produce few symptoms. This has been found with cysticerci, for example. Gliomata, also of soft consistency, do not produce symptoms in proportion to their size and rapid growth. This seems to have been true of those which extended almost the entire length of the cord. As to location, those outside the dura mater usually compress the cord less than those within it. The same is true of tumors in the more spacious parts of the vertebral canal—the middle and lower parts of the lumbar region.

It is to be remembered, as regards symptomatology, that some of the secondary effects of tumors, as localized acute myelitis, hæmorrhage into or about the tumor, are sudden in onset, and that, therefore, the clinical history, which is mainly that of gradual progression of symptoms, may present acute exacerbations, often followed by temporary improvement.

Etiology.—Some tumors, as gumma and tubercle, are due to diathetic conditions. In case of the latter, tubercles are almost always found in the lungs or the brain, often in the spinal meninges. Carcinoma is almost always secondary. Parasitic tumors—echinococci and cysticerci—have their usual cause. Beyond this the causes of intraspinal tumors are very obscure. Injuries—blows to the spine, etc.—seem often to be the etiological factor. Exposure, nervous shocks, etc., have been assigned as causes, though their influence in that direction is doubtful.

Symptoms.—Usually the first symptom, and the most prominent one throughout the course of the disease, is pain. This is often intense, and of a shooting, boring, or tearing character. In the beginning it is commonly limited to one side, and radiates along the course of the nerves given off at the level of the tumor. It may be thus localized on one side for a long time before it affects the other side or extends to other parts of the body. Such pain is due to irritation of the spinal roots, and is chiefly produced by tumors of the membranes. On the other hand, in intramedullary tumors, when the substance of the cord is directly irritated, the earliest pains may be in lower parts of the body, and not at the level of the tumors.

There is often pain in the back over the seat of the tumor, also tenderness to pressure. The pain may be increased by movement of the spine, especially if made in such a manner as to compress the tumor. Such movement may produce not only local, but also excentric pain. The latter symptom is probably found in proportion as the meninges, and especially the bone, are involved in the morbid process.

In addition to the pain there is often hyperæsthesia or paræsthesiæ—numbness, tingling, formication, etc.—in

Spinal Cord.

the painful area, and frequently a sense of constriction, or girdle sensation, near the level of the tumor.

Along with the symptoms of sensory irritation just described there are often signs of motor irritation—muscular spasms. They are more marked with tumors of the membranes than with those of the cord. There is often rigidity of the muscles of the back opposite the lesion, sometimes spasms of the abdominal muscles, and not infrequently spasms, even contractures, of the limbs. The latter are sometimes due to irritation of the spinal roots. In other instances they are late manifestations, and due to secondary changes in the cord.

Paralysis is a common symptom, but it usually appears after irritation symptoms have been present for some time. Motor and sensory paralyses may appear at the same time, or one may appear before the other, the motor more frequently preceding, although this depends upon whether the anterior or posterior portion of the cord is first affected by the tumor. The paralysis is usually gradual in its development, beginning with paresis of one member, which increases to paralysis, extends to the other side, and finally involves every part below the seat of lesion. If the tumor is in the cervical region the paralysis usually begins in the arm, though sometimes it appears first in the lower extremity; but usually the four extremities and the trunk finally become paralyzed. When the paralysis gradually increases from paresis to complete paralysis it is not liable to any improvement. But the paralysis does not always progress in this manner. Sometimes there is a sudden and considerable increase of the symptoms, due to an acute myelitis about the tumor, or to hæmorrhage. If the lesion be in the cervical region, sudden paralysis of the four extremities may occur. In such instances there is often subsequent amelioration of the symptoms. The anæsthesia, like the motor paralysis, is usually partial at first, and gradually becomes complete. It generally corresponds in distribution to the motor paralysis. But in some cases of unilateral lesion we have the picture presented by spinal hemiplegia, viz., motor paralysis with hyperæsthesia on one side, and anæsthesia on the other. In that case there is usually anæsthesia at the level of the tumor on the side of motor paralysis, due to injury of the posterior spinal roots. A striking feature often presented is the presence of severe pain in areas of profound anæsthesia. This condition has been termed anæsthesia dolorosa.

Ataxia has been observed in some cases where the posterior columns were compressed. The infrequency of this symptom is, probably, to be accounted for by the existence of the motor paralysis.

Atrophy of muscles is found to the extent that the anterior spinal roots are destroyed, or the anterior cornua are affected, by the secondary myelitis. It is always an indication of the level of the tumor. If the latter be in the upper part of the cervical enlargement, the atrophy is chiefly in the muscles of the upper arm; if in the lower part of the cervical enlargement, in the muscles of the forearm and hand; if in the dorsal cord, in the muscles of the trunk; if in the upper lumbar region, in the muscles of the hip; if in the lower lumbar enlargement, in the muscles of the leg. The extent of the atrophy is especially great when the tumor involves the lumbar cord or the cauda equina, on account of the number of nerves likely to be compressed. In other instances, too, the extent of atrophy may be considerable, because the secondary myelitis often extends for some distance below the tumor, and chiefly in the gray matter.

The electrical reactions are altered only in the atrophied muscles. In these the reaction of degeneration is more or less distinctly marked. In other paralyzed muscles the electrical reactions are normal. The state of the reflexes varies in different parts of the body. In the parts corresponding to the level of the tumor, where muscular atrophy is found, they are usually abolished, while in the lower part of the body both skin and tendon reflexes are increased, and there are often, at the same time, the other phenomena of spastic paralysis. Thus, if the tumor be in the cervical region, the skin and tendon reflexes of the upper extremities may be abolished, while those of the trunk and lower extremities are much exaggerated. If in the dorsal region, the skin reflexes of the thorax or abdomen may be abolished, the reflexes of the lower extremities exaggerated. If in the lumbar region, the patellar tendon reflexes, etc., are abolished; and if the lesion extend sufficiently low in the cord, all the reflexes in the lower extremities may be abolished.

In addition to those already mentioned, other symptoms of profound disease of the cord may be found. Vaso-motor manifestations—heat, more frequently coldness, in the paralyzed extremities, sometimes œdema; symptoms on the part of the rectum and bladder—incontinence of fæces and urine, cystitis, pyelitis, etc.; genital symptoms—impotence, priapism, etc., and decubitus, are more or less common.

A few words as to the peculiar symptoms of tumors at different elevations of the cord. Those in the cervical region are most likely to be attended by rigidity of the spine. They may produce respiratory symptoms, as cough and dyspnœa, also pupillary symptoms, contractraction or dilatation. If in the uppermost part of the cord, symptoms on the part of the cranial nerves may appear—dysphagia, disturbances of speech, sometimes optic neuritis. Tumors in the dorsal region can often be more exactly localized than those in the cervical or lumbar region, because the nerves of this part are not so crowded and do not unite in plexuses. Tumors in the lumbar region of the cord more frequently cause bedsores and paralysis of the bladder and rectum than those in other parts of the cord. The same is true of tumors of the cauda equina. The vesical symptoms are always early, and the paralysis of the bladder is likely to be very marked. When there is more than one tumor, the symptoms of lesions in different parts of the cord may appear. When their number is multiple, the symptoms of some of the tumors may be concealed by those of others.

In a general way, differences may be noted in the symptoms of tumors of the cord and of the membranes. The root symptoms are usually earlier and more severe with tumors of the membranes, while the cord symptoms come on at a later period. Pain, tenderness, and rigidity of the spine, as well as increase of pain on movement, are more common in tumors of the membranes. On the other hand, cord symptoms, paralysis, etc., and especially muscular atrophy, are usually earlier manifestations and more extensive in tumors of the cord.

The course of the disease is variable, depending upon the location, rapidity of growth, etc., of the tumor. Usually pain in a limited part on one side of the body is the earliest symptom, and months or years may pass before other symptoms appear. The paralysis usually begins as a paresis, and increases gradually in extent and intensity. The symptoms may progress steadily, or may be stationary for a longer or shorter time, or there may be a sudden increase of symptoms, often followed by improvement. Sometimes such different periods may alternate with one another. Cystitis and decubitus are usually late manifestations. The duration of the disease is from six months to eight or ten years or more. The average duration is from one to three years.

Diagnosis.—The diagnosis must be based on, firstly, the presence at the same time of both severe irritation symptoms—severe pain, muscular spasm, etc.—and paralysis; secondly, the gradual increase both in the intensity and extent of the symptoms, especially the indications of lateral extension of the disease from one side of the cord to the other; thirdly, local pain, tenderness, and immobility of the spine in the neighborhood of the tumor; also increase of pain on movement. The knowledge of causal relations may assist in the diagnosis. A history of constitutional syphilis should arouse a suspicion of gumma in the cord or membranes. With a primary cancer of the breast, and the clinical picture of paraplegia dolorosa—paraplegia with intense neuralgic pains—there can scarcely be any doubt as to the presence of intraspinal carcinomatous deposits.

Yet it must be acknowledged that it is often difficult or impossible to diagnose the presence of tumors. If soft, and slow in growth, they produce scarcely any symp-

toms. In others the clinical history presented is very obscure. Especially in the beginning, when pain may be the only symptom, is the diagnosis doubtful.

The diseases most likely to be confounded with intraspinal tumors are tumor or caries of the vertebræ, some painful forms of myelitis, and multiple neuritis. In the first there are more pronounced symptoms of disease of the bone, and slighter symptoms of disease of the nervous structures, and deformity appears, sooner or later, to clear up the diagnosis. In myelitis the pains are usually less severe, there is rarely the same kind of extension of symptoms, and the local pain, tenderness, rigidity, and pain on movement of the spine are rarely, if ever, found. In multiple neuritis the tenderness to pressure over the course of the nerves should be a valuable guide in forming a diagnosis.

After a tumor has been diagnosed it becomes next a question as to its locality and nature. The location of the tumor is to be determined by the height of the paralysis and the presence and location of the localizing symptoms—pain, spasm, muscular atrophy, and abolished reflexes. The nature of the tumor may be inferred from the presence of certain systemic conditions, syphilis, tuberculosis, or cancer; or of tumors, neuroma or sarcoma, in other organs. If none of these conditions is found, we can only be guided in our surmises by the general fact that the most common tumors in the cord are glioma and tubercle; in the membranes, sarcoma, fibroma, and gumma.

Prognosis.—The prognosis of intraspinal tumors is exceedingly grave. Only in cases of syphilomata is there much prospect of a cure, and if symptoms have been present a long time, treatment may often fail, even in these cases. Tumors of a malignant type usually cause the greatest suffering, and run the most rapid course. Tumors in the cervical region are likely to run a more rapid course than those of the cauda equina, where there is more free space and the nervous structures are of less vital consequence.

Treatment.—In cases of syphilomata very active treatment with both the iodides and mercury should be instituted. The same treatment should be tried where there is any suspicion of syphilis, for these are the only cases in which a cure can be hoped for. Beyond this the chief consideration is to afford the patient relief by the administration of anodynes. As the disease is often of long standing they must be carefully administered.

Since this article has been in type, Gowers and Horsley have reported the successful removal of a tumor (*British Med. Jour.*, January 28, 1888). The more precisely a local diagnosis can be made, and the less the cord is involved in the growth, the more hopeful will be the outlook for such operations in the future.

Philip Zenner.

SPINAL NERVES are those which emanate wholly from the spinal cord. They are more regular in their structure and arrangement than are the cranial nerves, arising always in pairs from either side of the spinal cord, each nerve having two roots connected with the horns of gray matter, a posterior or sensory root upon which a ganglion is developed, and an anterior or motor root which has no nervous connection with the ganglion. They unite immediately beyond the ganglion to form a mixed trunk.

Comparing this now with the cranial nerves, it will be seen that there is no perfectly clear and well-marked distinction of anatomical characters, for the hypoglossal and spinal accessory arise in part from the spinal cord, and in lower vertebrates they are unquestionably spinal nerves. In human embryos the hypoglossal has a posterior root on which a ganglion is formed. Yet it may be said that on the whole the cranial nerves are formed upon a more primitive type. Animals of a simple structure, like the ascidians, from which vertebrates are derived, have for a body a simple muscular sac, and the nervous apparatus consists of a central ganglion from which proceed two sets of nerves, one conveying impressions from the external surface of the ganglion, another distributing impulses from that ganglion to the muscles which contract the sac. The two sets of nerves, afferent or sensory, and efferent or motor, are entirely distinct, resembling in this the majority of the cranial nerves in man. It would seem that the greatly accelerated development of the anterior pole of the body mainly relates to the nervous system and its coverings, and that the peripheral nerves have not been able to acquire that regularity and symmetry which characterize the other parts of the body, where the development has been slower and the stability greater.

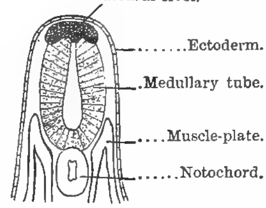

Fig. 3656.—Cross-section of Embryo of Chick before the Appearance of the Spinal Nerves. (After Marshall.)

In the lowest vertebrates the spinal nerves arise by a single root, which conveys both sensory and motor impulses.

In fœtal life these nerves originate as outgrowths from the central nervous system. At the time the medullary groove folds over to form the neuro-central canal, there arises directly along the edges of the seam made by the union a longitudinal band of cells known as the neural crest. (See Fig. 3656.)

This becomes larger at points corresponding to the segments of the body, and pushes out processes laterally which become the posterior nerve-roots. At first these are connected across the back of the cord by means of the neural crest, but as they increase in size they acquire a secondary attachment near the posterior horns of the spinal cord and the crest disappears. The ganglion soon appears as a swelling upon the budding root, and may be covered by an outgrowth from the posterior horns of the cord. (Fig. 3657.)

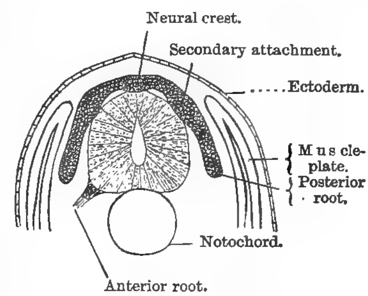

Fig. 3657.—The Same, at a later Stage. (After Marshall.)

Duval, however, considers that it is developed independently, and afterward becomes united to the cord through the posterior root, and thus explains the fact that the trophic centre for the posterior root resides in the ganglion, while that for the anterior root is, as is well known, in the anterior horn of the cord. The motor roots arise later and separately, as distinct extensions from the ventral surface of the cord (Fig. 3658).

The spinal nerves are regularly arranged in pairs, which correspond to the segments or metameres of the vertebrate body. Thirty-one of these pairs are satisfactorily made out, and Rauber has recognized the rudiments of two other pairs which do not (as far as known) leave the spinal canal, but remain in the cauda equina of the spinal cord, the atrophied vestiges of a period when the posterior pole of the body was more developed than at present.

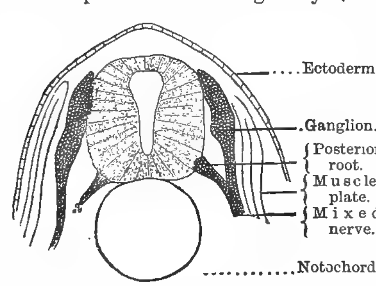

Fig. 3658.—The Same, when the Formation of Nerve-roots is Completed. (After Marshall.)

The nerves pass from the spinal canal through the intervertebral foramina, and are divided into cervical, dorsal, lumbar, sacral, and coccygeal groups, corresponding to those regions of the spine. It was the original intention of Willis to have the names correspond invariably to

the vertebra *under* which the nerve passes out. Thus the fifth lumbar nerve passes out between the fifth lumbar vertebra and the sacrum, and the fifth sacral between the sacrum and the coccyx. He considered the suboccipital nerve, which passes out between the occipital bone and the first cervical vertebra, as a cranial nerve. Vicq d'Azyr pointed out that in its origin and anatomical character it was a spinal nerve, and, therefore, added it to the cervical nerves—which deranged the scheme for that region. The eighth cervical nerve, therefore, emerges below the seventh cervical vertebra, and so on. It will be evident that this method of readjusting the nomenclature occasioned less change in the existing terms than any other scheme would have done. Coues has proposed, however, to rearrange the entire series, and commencing at the first cervical, to renumber all the nerves, naming each from the vertebra *over* which it passes out. This would not only be an advantage in nomenclature, but also represent more accurately the metameric relations of the nerves. As the body has grown proportionately faster than the cord, the central attachment of the nerves is invariably higher than their peripheral distribution.

According to the generally accepted arrangement, the nerves are classified in pairs, as follows:

Cervical nerves	8
Dorsal nerves	12
Lumbar nerves	5
Sacral nerves	5
Coccygeal nerves (two being rudimentary)	3
Total	33

The size of the posterior roots is greater than that of the anterior, as is the case with sensitive nerves generally. It appears to be necessary to have a large number of independent fibres for the conveyance of the multiform impressions from the outer world, while, after these impressions have been transmitted into comparatively simple motor impulses, a less number of separate tracts is required. Stilling carefully determined the comparative area of the cross-sections of the roots in a female subject of twenty-six years, and found the total of the anterior roots to be 35 to 36 square millimetres, while the posterior roots amounted to from 54 to 57 square millimetres.

There is also a variation in the size of the nerve according to the activities of the part of the cord from which it is given off. Those nerves which supply the extremities are necessarily much larger than those which merely go to the body-wall. Not only is the area to which they go larger, but the differentiation of organs is carried to a far greater extent. These nerves are given off opposite the cervical and lumbar enlargements of the cord. According to Stilling, the sixth cervical exceeds the others at the cervical enlargement, while the second is the largest of the sacral nerves.

The ganglia upon the posterior roots are usually found in the intervertebral foramina, except in the case of the sacral and coccygeal nerves. The point of emergence of the trunks of these is a considerable distance below the origins of the nerves, and the ganglia are withdrawn within the spinal canal by the downward growth of the column, and lie between the dura mater and the wall. The size of the ganglia is in proportion to that of the nerve upon which it is found.

The characters which have been given for the spinal nerves are not entirely invariable. There may be certain fibres which do not leave the spinal canal. These may pass directly from one pair of roots to the other with outward convexity (ansa centripetalis, Hilbert), in which case they appear to be related to the fibres of recurrent sensibility, or they may pass from one root with an outward concavity (ansa centrifugalis) to the root next above or below, without connection with the cord. The meaning of this is not very clear; but it should be remembered that fibres may be displaced from their origin in the course of development in such a way as to deceive one as to their actual course. For instance, there is no doubt that fibres run down along the main trunk of the facial nerve, and then turn backward at an acute angle to enter the chorda tympani. It is not by any means infrequent to find a considerable variation in the relative size of contiguous nerves, the fibres usually assigned to one apparently passing to the other. Fine fibres not connected with the nerve-roots may arise directly from the spinal cord and supply the meninges of the vertebral canal. The ganglia may vary. Instead of a single collection of gray matter, there may be several masses scattered along the posterior root in an almost continuous chain, as if in the embryonic development of the root from the cord there had been a continuation outward of the gray matter of the posterior horn. If we attempt to trace the fibres of the roots to their intimate connections in the cord, we find the subject involved in difficulty. The fibres of the sensitive roots on entering the postero-lateral groove may be divided into two groups, which pass on either side the substantia gelatinosa. The external set appear to ascend somewhat, and then either join the fibre-plexus or pass to the anterior horn; the internal set pass, some to Clarke's column, some to the opposite side through the gray commissure, and some pass upward and are lost.

The fibres belonging to the anterior roots are many of them directly derived from the motor cells of the anterior cornu. Some of them, however, come from the lateral column of the cord (crossed pyramidal tract), and we have no absolute anatomical demonstration of their origin.

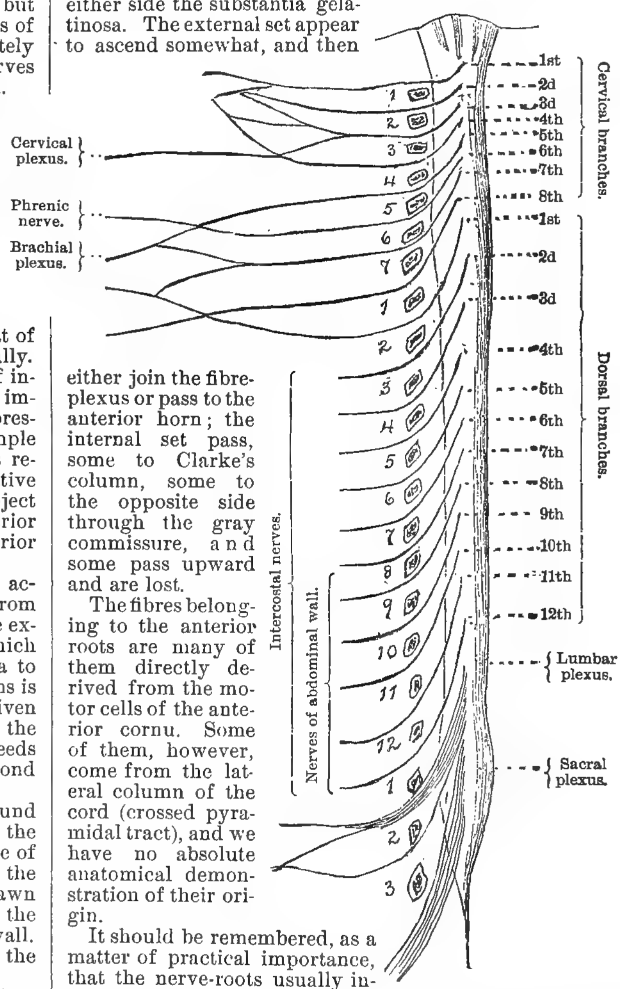

FIG. 3659.—Diagram showing the Relation between the Spinous Processes and the Origin of the Spinal Nerves.

It should be remembered, as a matter of practical importance, that the nerve-roots usually incline downward somewhat from their point of emergence to reach the intervertebral foramina, owing to the lengthening of the canal already adverted to. The first and second cervical are exceptions, the former ascending slightly, and the latter being horizontal. Those below increase in their obliquity from above downward. Thus, while the lower cervical nerves leave the canal the space of an entire vertebra below their emergence from the cord, the dorsal nerves have an interspinal passage of from two to three vertebræ; and for the lumbar and sacral and coccygeal nerves it is still greater, for the cord ends at the first lumbar vertebra. Because of this fact it would be quite

possible to have a lesion affecting a nerve in the spinal canal considerably above its point of emergence, and symptoms might be caused which would be improperly referred to a lower situation if this fact was not taken into account.

The following table, from Tillaux, shows the relation between the spines of the vertebræ and the origins of the nerves.

Nerve.	*Relation to Vertebral Spines.*
Cervical I.	At level of foramen magnum.
II.	A little below the occipital bone.
III.	A little below the middle of the space between the occipital bone and the spinous process of the axis.
IV.	At the spinous process of the axis or above.
V.	Third vertebral spine or above.
VI.	Below 3d, but above 4th.
VII.	From spine of 4th and above, to spine of 5th.
VIII.	From spine of 5th to above spine of 6th.
Dorsal I.	Above spine of 6th to the 7th.
II.	Seventh cervical to 1st dorsal.
III.	From 1st dorsal to middle of interval between it and 2d dorsal.
IV.	From just above to a little below 2d dorsal.
V.	From just above to a little below 3d dorsal.
VI.	From just above to a little below 4th dorsal.
VII.	Fifth dorsal to above.
VIII.	From 5th dorsal to a little above 6th.
IX.	From 6th dorsal to a little above 7th.
X.	From 7th dorsal to a little above 8th.
XI.	From 8th dorsal to a little above 9th.
XII.	From 9th dorsal to a little above 11th.

The five lumbar nerves arise successively from the spine of the 11th dorsal vertebra to the spine of the 12th.

The five sacral nerves and the coccygeal arise successively from the spine of the 12th dorsal vertebra to that of the 1st lumbar.

It follows from this table that any lesion which paralyzes the neck and limbs must be above the 5th cervical vertebra. The phrenic nerve cannot be affected unless the nerves from which it arises (3d and 4th cervical) are involved. The centre for them is above the axis. A luxation of that vertebra is not, therefore, necessarily immediately fatal. A dislocation of the atlas is at once followed by death.

A lesion at the 12th dorsal vertebra paralyzes the sacral plexus at the 11th dorsal, the lumbar, and sacral. If at the 5th dorsal, the abdominal walls are also paralyzed; and at the 3d dorsal the paralysis will reach the 3d intercostal space. If at the 6th or 7th cervical, all the intercostal spaces are paralyzed. These relations are also illustrated in Fig. 3659.

After leaving the intervertebral foramen the mixed trunk soon divides into branches which have special relations to the different portions of the body-wall. A dorsal branch (Fig. 3660) goes to supply the muscles and structures surrounding the neuro-central tube. Some sensitive fibres, which appear to relate to this branch, do not leave the main trunk of the nerve, but run back along the motor root and supply the membranes of the cord. It is those that produce the phenomena of "recurrent sensibility" which occur when the motor root is cut. A neutral branch goes to the muscles of the general body-wall (somatopleure), and a visceral branch connects with the great sympathetic cord and proceeds to the alimentary canal and its annexes (splanchnopleure).

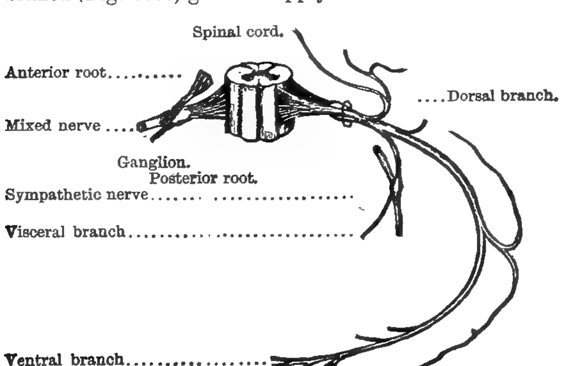

FIG. 3660.—Diagram of a Spinal Nerve.

The visceral branch gives off a fine twig, which, uniting with another from the sensory root, forms the nervus sinu vertebralis of Luschka, which passes in at the intervertebral foramen and supplies the walls of the canal and the bodies of the vertebræ.

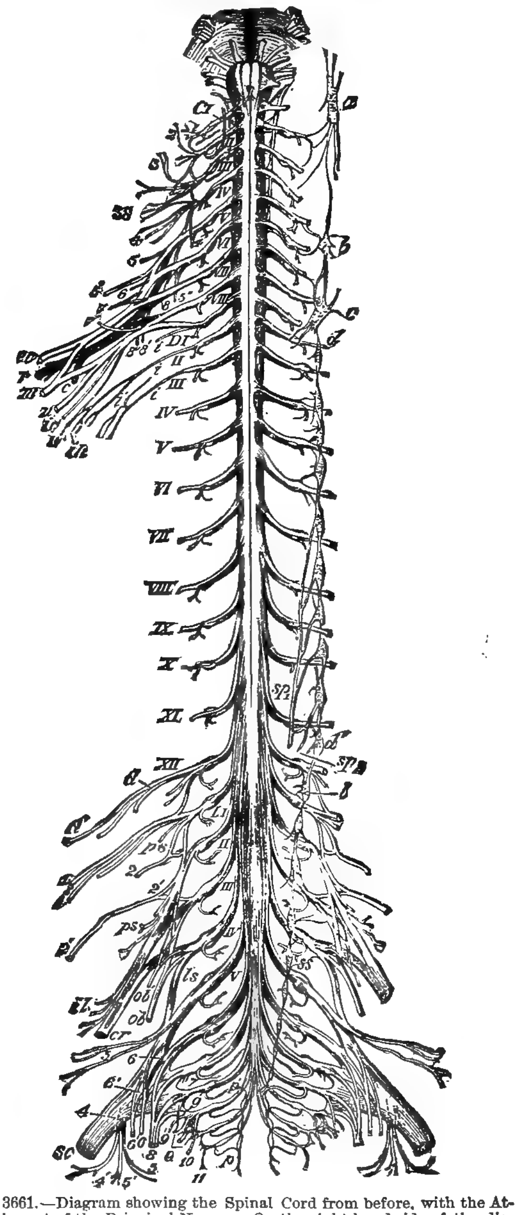

FIG. 3661.—Diagram showing the Spinal Cord from before, with the Attachment of the Principal Nerves. On the right-hand side of the diagram the connections with the sympathetic nerve are shown; on the left-hand side, the plexuses of the anterior roots. (From Ferrier.)

The dorsal or posterior branches are usually much smaller than the ventral, corresponding to the area of the tube for which they were originally intended; but when that tube expands greatly, as in the cranium, the dorsal branches at once increase greatly in size, and that of the first cervical nerve exceeds the ventral branch. They supply the skin and deep muscles on the posterior part of the neck and the back, including the lumbar and sacral regions and a portion of the gluteal region. Two of

Spinal Nerves.

these nerves only have received special names. These are the first and second, known as the suboccipital, and the great occipital nerves. These supply the posterior part of the neck and scalp as far as the vertex. In disease of the cervical vertebræ they may be affected and occasion persistent pseudo-neuralgic pains.

The ventral or anterior branches (see Fig. 3661) form the principal nerves of the body and limbs. They do not usually pass singly to their destination, but after a short course unite with each other to form plexuses, in which the original fibres are mingled intimately. These plexuses form two grand divisions, corresponding to the chief nerves; the upper one, constituted by the anterior branches of the cervical and the first dorsal nerves, is known as the cervico-brachial plexus; the lower one, made up of all the lumbar, sacral, and coccygeal nerves, is called the lumbo-sacral plexus. These, again, have been subdivided into portions which correspond to the parts which they supply. These divisions are shown in the following table, modified from Schwalbe:

Pl. cervico-brachialis	C. 1–4 = cervical plexus.	
	C. 5–8, D. 1 = brachial plexus.	
Pl. lumbo-sacralis	L. 1–3, L. 4 = lumbar plexus.	
	Plexus ischiadicus: L. 4, L. 5, S. 1, 2, 3, 4.	= Sacral plexus.
	Plexus pudendalis, or pudendo-hæmorrhoidalis: S. 3, 4, 5 (S. 2).	= Sacral plexus.
	Plexus coccygeus, or sacro-coccygeus: S. 5, Co.	= Sacral plexus.

C., cervical; D., dorsal; L., lumbar; S., sacral; and Co., coccygeal nerves.

It will be seen that there remain eleven dorsal nerves that are not classed as assisting in the formation of the plexuses. It should be remembered, however, that both the second and eleventh dorsal send branches to the nerves derived from the plexuses, and that they might therefore properly be included in the table. The anterior roots of the dorsal nerves generally pass forward and form the intercostal nerves.

By far the most important of these plexuses are the brachial and the ischiadic, which supply the great nerves for the limbs. The upper extremity is supplied from five spinal nerves, while to the lower and larger limb no less than nine contribute.

The intermingling of nerve-fibres in the plexuses is so great that the nerves which are given off as ultimate branches have most of them an origin from several of the spinal nerve-roots. Many attempts have been made to thoroughly trace out the origin of each nerve. It is almost impossible to do this, and, because of the intimate intermingling of the fibres, different observers have obtained results which are not entirely identical.

It is probable that, as far as regards the formation of plexuses, that the individual variations are very great. The brachial plexus is by far the most regular, because of its peculiar relations to the axillary artery, yet it is certainly very variable both in its composition and its arrangement—so much so that the purely typical form is rarely seen in the dissecting-room. In the formation of plexuses it would seem that there is merely a continuation of a tendency which can be noted throughout the nervous system. Within the sheath of every large nerve the fibres are constantly interweaving among each other

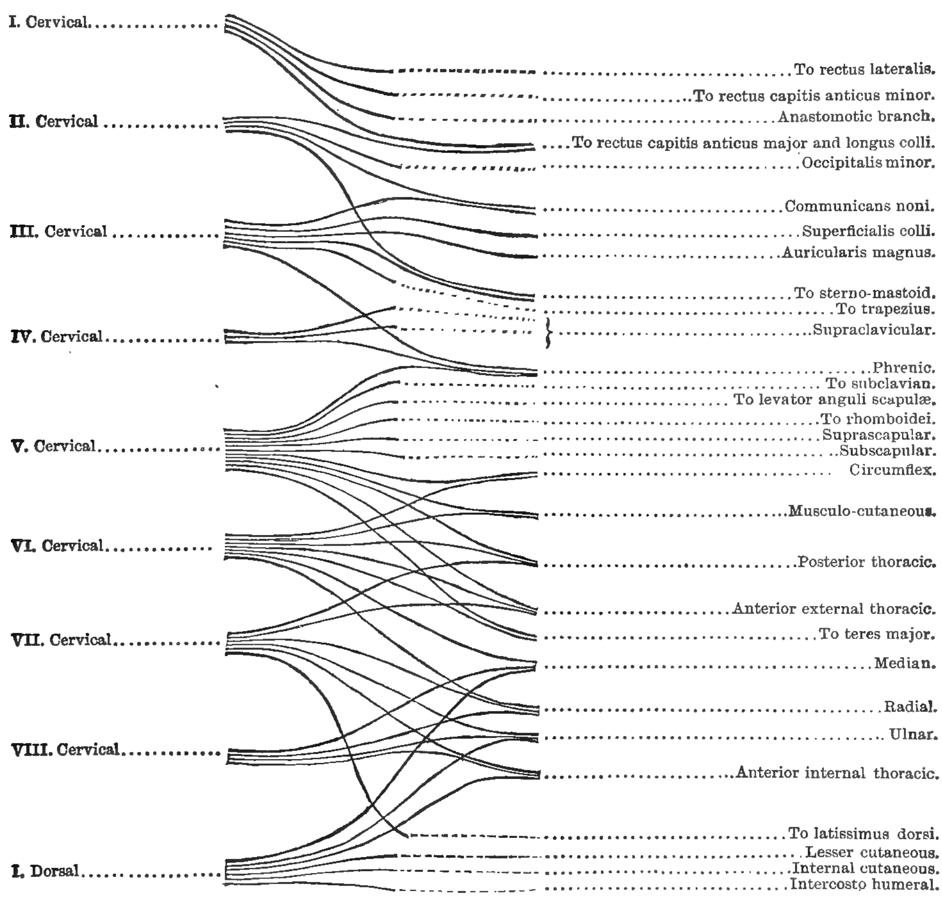

FIG. 3662.—Diagram showing the Origin of the Principal Nerves of the Cervico-brachial Plexus. (After Féré.)

in an irregular manner, so that the relative arrangement changes indefinitely, even in a very short distance.

The question to be solved, however, is not whether the ultimate nerves arise from certain definite cords of the plexuses, but from what part of the spinal cord they can be derived. Féré, after combining the data of others with those from his own dissections, prepared diagrams similar to those shown in Figs. 3662 and 3663, and they may be said to represent our present knowledge on this subject. In studying lesions of the cord it is often necessary to determine from the symptoms the point at which the disorder is situated, and these diagrams permit us to ascertain the approximate area of the cord which is affected when symmetrical impairment of motility or sensibility occurs.

Our knowledge of the muscular system is not sufficient to enable us to fully understand the meaning of this time that the buds for the limbs were formed by the fusion of lateral elements from the somites of the trunk, the relative arrangement of the musculo-nervous canal could probably be cleared up. It will be necessary to await further embryological investigations before this obscure subject can be fully elucidated.

The cervical plexus is formed by the anastomoses of the anterior branches of the first four cervical nerves together with the hypoglossal. The loop supplied by the latter cannot, however, be traced to the hypoglossal nucleus, but is really derived from the first and second cervical nerves, as will be seen in Fig. 3664. This loop supplies all the muscles of the jaw and infrahyoid region, usually assigned to the hypoglossal, leaving for that nerve merely the task of providing motor influence for the intrinsic fibres of the tongue. The hypoglossal side of the loop is known as the descendens noni nerve, and

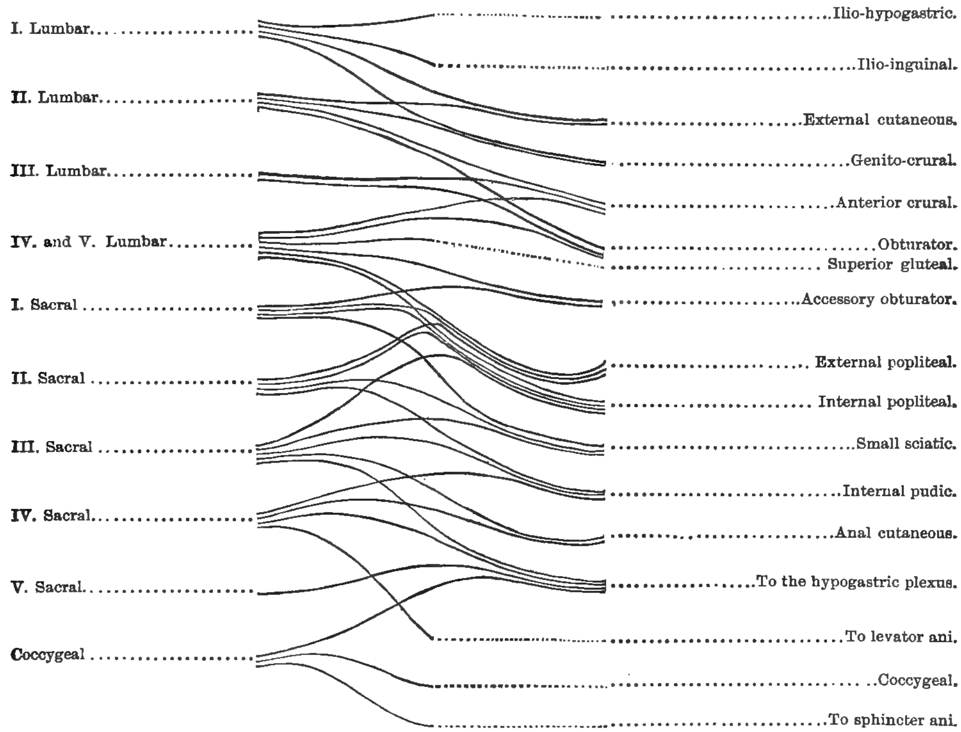

FIG. 3663.—Diagram showing the Origin of the Principal Nerves of the Lumbo-sacral Plexus. (After Féré.)

arrangement. It only appears from a study of the diagrams that those nerves which represent the widest range of activity are those which have the largest area of origin from the cord, and that certain nerves appear to be mere appendages to others. Examples of this may be seen in the internal cutaneous nerves of the arm, which seem to belong to the ulnar, and the obturator, which is related to the anterior crural. It is noticeable that the nerves which supply the distal ends of the limbs are derived from roots farther from the brain than those which supply the proximal ends of the same limbs. As a general rule (subject, however, to many exceptions), the muscles are innervated by the same nerve which supplies the skin over their insertions.*.

It has been surmised that this plexiform arrangement is necessary in order to supply the muscles and other organs with twigs from various sources, so that if one source of supply is injured or cut off the other may be used. It is not quite clear how this can be done. If the entire history of development were known, from the is of some surgical interest, as it usually lies directly on the carotid sheath, and may be in the way when ligation of that vessel is attempted.

The following table[1] gives a general view of the composition of the cervical plexus :

Cervical Plexus of Nerves.

Anterior branch of 1st CERVICAL nerve. Anterior branch of 2d CERVICAL nerve. Anterior branch of 3d CERVICAL nerve. Anterior branch of 4th CERVICAL nerve.	CERVICAL PLEXUS.	SUPERFICIAL BRANCHES (integumentary).	Ascending set.		Occipitalis minor. Auricularis magnus. Superficialis colli.
			Descending set.		Supra-clavicular branches.
		DEEP BRANCHES.	Internal set.	Communicating.	
				Muscular.	Rect. cap. ant. major. Rect. cap. ant. minor. Rect. cap. lateralis.
				Communicans noni.	
				PHRENIC.	
			External set.	Muscular.	Sterno-mastoid. Levator anguli scap. Trapezius. Scalenus med.
				Communicating.	

* This is generally known as Hilton's law, but it was formulated by Peyer and W. Krause, some time previous to the publication of Rest and Pain.

Spinal Nerves.

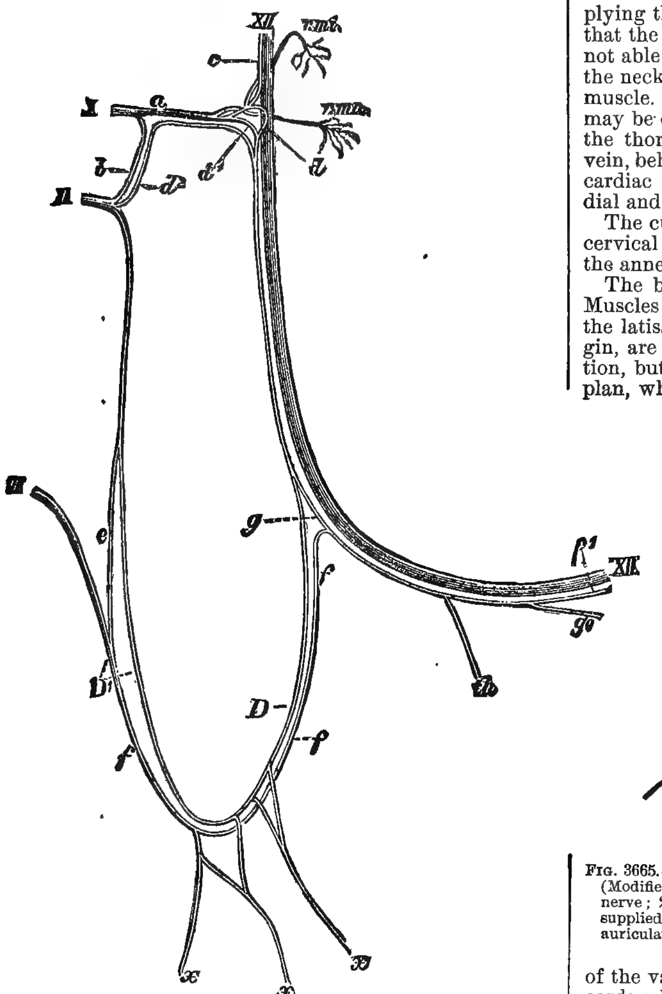

FIG. 3664.—Connection of the Hypoglossal with the Cervical Nerves. (Hall.) XII, Hypoglossal nerves; I, II, III, anterior branch of cervical nerves; D, D¹, rami communicantes noni; *a*, branch of first cervical nerve, which sends a twig, *c*, centrally upward, and gives off twigs *r. ma*, *r. mi*, to the anterior recti muscles; *d*, *d*¹, *d*², descending branches that accompany the hypoglossal; *b*, *e*, loops between cervical nerves; *f*, *f*, descendens noni; *x*, *x*, *x*, twigs for infrahyoid muscles; *g*, the bundle from first and second cervical, uniting with *f*¹ from third cervical; *th*, branch to thyro-hyoid; *ge*, branch to genio-hyoid.

The most important nerve, clinically, is the phrenic, as when it is injured paralysis of the diaphragm immediately ensues, for though it is not the only nerve supplying that muscle, its influence is so much predominant that the other nerves (branches from the intercostals) are not able to do the work. Its most exposed situation in the neck is where it lies in front of the scalenus anticus muscle. It may here be wounded by a stab. It also may be compressed by an aneurism when it passes into the thoracic cavity between the subclavian artery and vein, behind the sterno-clavicular articulation, or by pericardiac effusion as it passes down between the pericardial and pleural cavities.

The cutaneous supply of the neck is derived from the cervical plexus, the areas being approximately shown in the annexed diagram, Fig. 3665.

The brachial plexus supplies the arm and shoulder. Muscles which morphologically belong to the arm, like the latissimus dorsi, although far removed in their origin, are supplied by it. It is subject to very great variation, but it nevertheless may be reduced to a general plan, which may be said to be typical. A great many

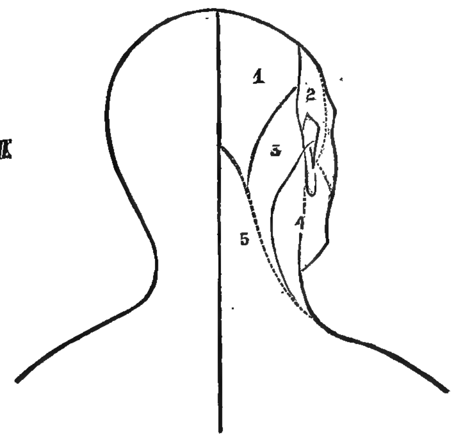

FIG. 3665.—The Nerve-supply of the Posterior Portion of Head and Neck. (Modified from Flower.) 1, Region supplied by the great occipital nerve; 2, region supplied by the auriculo-temporal nerve; 3, region supplied by the small occipital nerve; 4, region supplied by the great auricular nerve; 5, region supplied by the third cervical nerve.

of the variations depend upon the fact that the different cords which compose it may unite sooner or later than usual. Fig. 3666 shows a type to which all variations may be reduced. It will be seen that the 1st dorsal and 8th cervical are the first to unite. Then the 5th and 6th cervical combine, while the 7th remains free. There are thus formed three stems, which Schwalbe calls primary trunks. From each of these there is given off an anterior and a posterior branch. The three posterior branches unite to form a single cord, the anterior branch of the 1st and 2d trunks form another, while that of the 3d trunk remains ununited. There are thus formed three cords which have a definite relation to the axillary artery, lying posteriorly, externally, and internally from it. From these cords the main nerves are given off: from the external the musculo-cutaneous, and one branch of the median; from the internal the other branch of the median, the ulnar, and the internal cutaneous; from the posterior the radial (musculo-spiral) and the circumflex.

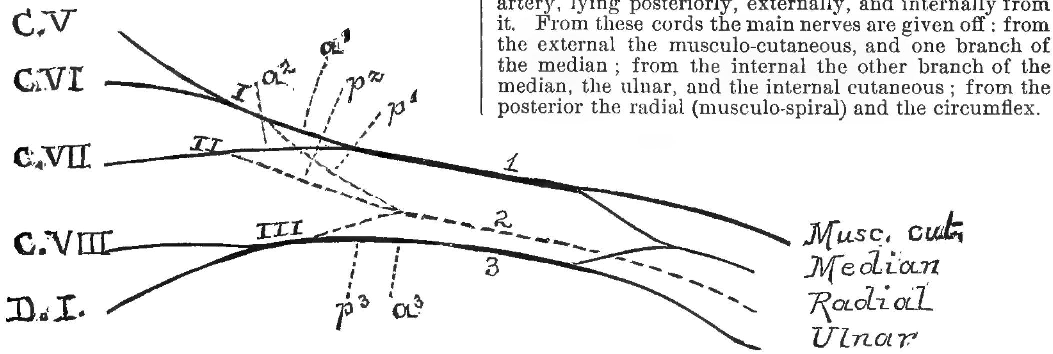

FIG. 3666.—Diagram of a Typical Brachial Plexus. (Schwalbe.) I, II, III, Principal trunks; a^1, a^2, a^3, anterior branches; p^1, p^2, p^3, posterior branches; 1, 2, 3, cords.

The following table[1] shows the other details of distribution of the plexus :

The Brachial Plexus.

Branches *above* the clavicle.	Posterior thoracic (*external respiratory nerve of Bell*).	
	Suprascapular........	Supraspinatus. Infraspinatus. Shoulder-joint.
	Muscular. (8).........	Rhomboidei muscles. Subclavius. Scaleni muscles. Longus colli. Levator anguli scapulæ.
	Communicating (to phrenic nerve).	
Branches *below* the clavicle.	From *inner* cord	Internal anterior thoracic. Internal cutaneous. Lesser internal cutaneous (Wrisberg's nerve). Inner head of median nerve. Ulnar nerve.
	From *outer* cord	External anterior thoracic. External cutaneous. Outer head of median nerve.
	From *posterior* cord.	1st subscapular nerve. 2d subscapular nerve. 3d subscapular nerve. Radial nerve. Circumflex nerve.

Rauber endeavors to simplify the plexus still more by considering the division as arising still further back. His scheme is shown in Fig. 3667. He divides each root at once into an anterior and posterior branch. The latter forms the posterior cord. The 8th cervical and 1st dorsal form the inner cord, then the 5th, 6th, and 7th unite to form the outer. There is thus a division of regions which control the entire arm.

The muscles of the dorsal region, extensors and supinators, are generally controlled by the radial, those of the palmar surface by the musculo-cutaneous above and the median below, the hand being divided between the median and the ulnar. The radial side of the arm is supplied by nerves which have a higher origin in the cord than the ulnar side. The thumb side of the hand is therefore to be considered as that which was originally directed forward.

An inspection of Fig. 3668 will show that a similar law governs the cutaneous nerves of the arm.

One of the mooted points in anatomy is the so-called antero-posterior symmetry of the limbs. Most anatomists hold that the radial side of the arm corresponds with the tibial side of the leg ; but others, among whom may be mentioned Wyman and Coues, suppose that the fibula and the radius are homologous. Wilder advances a theory that the limbs are reversed repetitions of each other, corresponding as an image in the mirror corresponds to the object producing the reflection. It will be seen that the distribution of nerves throws some light on this subject.

The lumbar plexus is buried in the fibres of the psoas magnus muscle, its branches appearing laterally from it or passing out below. The following table[1] shows its general distribution :

Anterior Divisions.	Lumbar Plexus.	
1st Lumbar nerve.	Ilio-hypogastric nerve. Ilio-inguinal nerve. Communicating to 2d lumbar.	Given off by the 1st lumbar nerve.
2d Lumbar nerve.	Genito-crural nerve. External cutaneous nerve. Communicating to 3d lumbar.	Given off by the 2d lumbar nerve.
3d Lumbar nerve.	Part of anterior crural nerve. Part of obturator nerve. Part of accessory obturator nerve. Communicating to 4th lumbar.	Given off by the 3d lumbar nerve.
4th Lumbar nerve.	Part of anterior crural nerve. Part of obturator nerve. Part of accessory obturator nerve. Lumbo-sacral cord.	Given off by the 4th lumbar nerve.

It controls the psoas and iliacus, and the great extensor and adductor groups of the thigh. It sends no muscular branches below the knee.

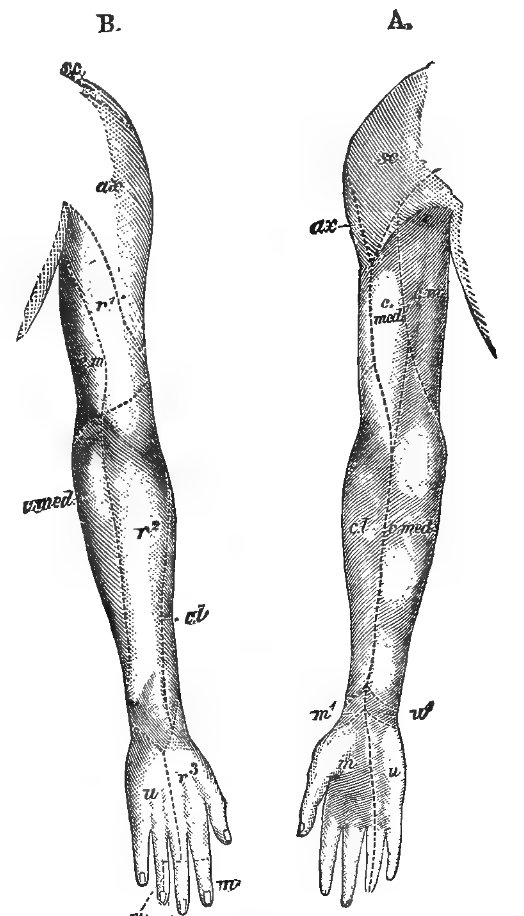

FIG. 3668.—Cutaneous Distribution of the Nerves of the Arm. *A*, Palmar aspect; *B*, dorsal aspect; *sc*, suprascapular nerves; *ax*, circumflex nerve ; *c.m*, lesser internal cutaneous ; *c. med*, internal cutaneous ; *c.l*, musculo-cutaneous ; *r*, radial ; *m*, median ; *u*, ulnar.

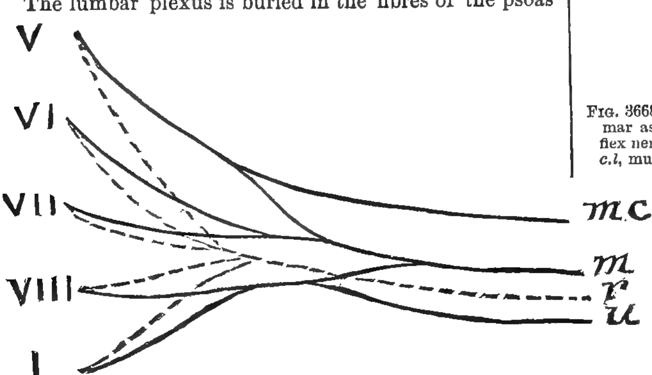

FIG. 3667.—Diagram showing the Plan of the Brachial Plexus, according to Rauber.

The sacral plexus, on the contrary, controls the great gluteal flexor and rotator groups of muscles, the thigh, and all the muscles below the knee. The cutaneous distribution (Fig. 3669) is such that the lumbar plexus (higher roots) generally innervates the anterior surface and tibial edge, while the sacral plexus supplies the posterior surface and the fibular edge. Thus the conclusion arrived at from comparative anatomy and embryology, that the tibial and radial bor-

ders of the two limbs are properly comparable, is here confirmed.

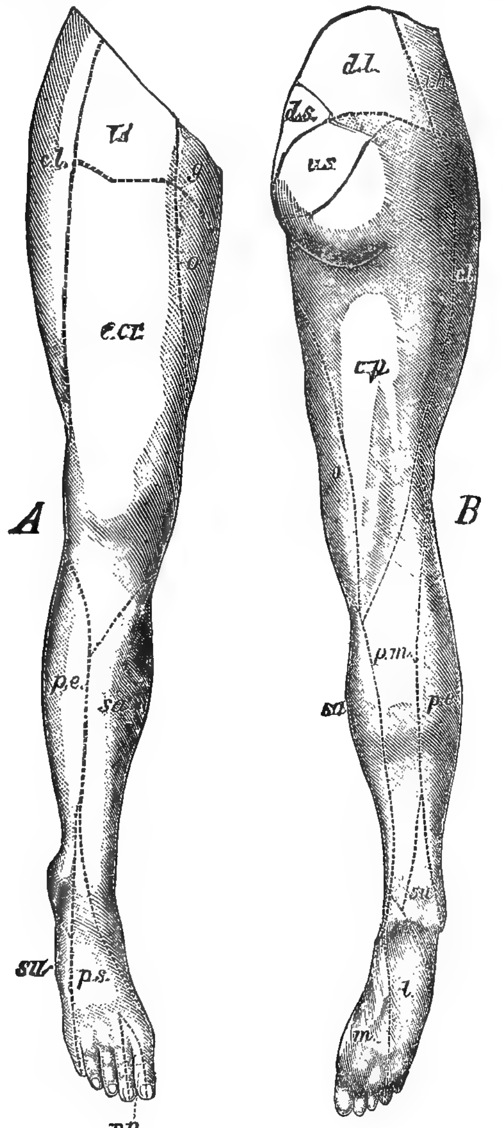

Fig. 3669.—Cutaneous Distribution of Nerves of Lower Extremities. *A*, Anterior view; *B*, posterior view; *d.l*, *d.s*, dorsal branches of lumbar and sacral nerves; *v.s*, inferior gluteal; *i.h*, ilio-hypogastric; *g*, ilio-inguinal; *l.i*, genito-crural; *c.l*, external cutaneous; *c.cr*, middle cutaneous; *o*, obturator; *c.p*, lower sciatic; *sa*, saphenous; *p.e*, external popliteal; *p.m*, post-tibial; *su*, saphenous; *p.s*, musculo-cutaneous; *p.p*, anterior tibial; *m*, internal plantar; *l*, external.

The general distribution of the sacral plexus is shown in the following table:[1]

Distribution of the Branches of the Sacral Plexus.

Superior Glutral.	*Superior* branch.		Gluteus medius muscle. Gluteus minimus muscle.
	Inferior branch.		Gluteus medius muscle. Gluteus minimus muscle. Tensor vaginæ femoris.
Muscular branches.	Pyriformis. Obturator internus. Gemellus superior. Gemellus inferior. Quadratus femoris.		
Articular branches.	To hip-joint.		
Small sciatic.	*Inferior gluteal* branch.		Gluteus maximus muscle.
	Inferior pudendal branch.		*Integument* of perineum. *Integument* of upper and inner part of the thigh. *Integument* of scrotum or labium.
	Cutaneous branch.	Ascending.	*Integument* over gluteus maximus muscle.
		Descending.	*Integument* of inner and outer sides of posterior aspect of the thigh.
Great sciatic.	Articular (to *hip-joint*).		
	Muscular........		Adductor magnus. Semimembranosus. Semitendinosus. Biceps flexor cruris.
	Terminal........		External popliteal. Internal popliteal.
Pudic nerve.	*Perineal*.........	*Cutaneous* or *superficial perineal.*	*Integument* of anal region, scrotum, penis, and labia. Sphincter ani muscle.
		Muscular	Muscles of the perineum.
	Inferior hæmorrhoidal.		
	Dorsal nerve of *penis.*		*Integument* of the dorsum and sides of penis. Branch to corpora cavernosa.

Frank Baker.

[1] Darling and Ranney: The Essentials of Anatomy.

SPLEEN, DISEASES OF THE.

Introduction.—It is now generally admitted that the only ascertained function of the spleen relates to the production of the white and to the destruction of the red blood-corpuscles. Physiologists adduce, in support of this view, the facts that the blood of the splenic vein contains a larger number of white corpuscles than that of the corresponding artery, particularly in cases of splenic leucocythæmia, and that the opposite numerical relations obtain with regard to the red corpuscles. Writers upon physiology also advance the theory that the spleen acts as a vascular diverticulum for the portal venous system, and conjecture, from the invariable presence of uric acid, leucin, and xanthin in the spleen, that this organ is the seat of various undetermined metabolic processes.[1] Since our knowledge of the physiology of the spleen is so meagre, it naturally follows that the relations of splenic diseases to morbid systemic conditions still constitute a *terra incognita* presenting a large and inviting field for original physiological, clinical and pathological research.

Most of the diseases of the spleen are, thus, acknowledgedly interesting rather as concomitants of other morbid conditions than because they exert any known direct influence upon the economy at large. On this account they are generally cursorily considered in systematic treatises upon clinical medicine, being regarded by many authors as of decidedly secondary importance. It is, however, desirable to emphasize the fact that splenic diseases often serve as trustworthy indices of other morbid states, and furnish valuable corroborative evidence of their existence at a stage when prophylactic measures may yet be successfully employed, or roborant treatment advantageously inaugurated.

The writer's opinion, that the spleen should be carefully interrogated in every clinical examination, influences him to preface this article by a few hints in regard to the methods of investigating the physical condition of this organ.

It is important that the diagnostician have definite ideas relative to the normal shape and position of the spleen, inasmuch as diseased conditions susceptible of diagnosis almost always betray themselves by alterations in one or the other of these physical features. The means of physical examination at the physician's command are inspection, auscultation, palpation, aspiration and percussion. The four former modes of investigation afford no assistance in the examination of the normal organ, while percussion gives only approximately correct information, as is evidenced by the discrepancies between the statements of different well-qualified observers. This diversity of opinion may be accounted for by the fact that the spleen varies very notably, in weight and size, in different healthy individuals, under varying conditions,

and at different ages. Gray states that the weight of the spleen at birth is, in proportion to that of the entire organ, as one to three hundred and fifty, and in adult life as one to from three hundred and twenty to four hundred, while the proportion in old age is as one to seven hundred. The same author gives the average weight of the spleen, in adult life, as seven ounces, and the length as five, the breadth as from three to four, and the thickness as from one to one and a half inches, respectively.[2]

One great source of difficulty in accurately outlining the spleen is the occasional superimposition of neighboring organs, viz., of the stomach in gastric tympanites or in the progress of normal digestion, of the colon in distention of that viscus, and of the lung in emphysema or in other pulmonary diseases.

Percussion shows, however, that the average normal adult spleen extends from the upper border of the ninth rib to the lower margin of the eleventh rib, where the splenic flatness imperceptibly merges into that of the kidney, and from about one and a half inch to the left of the spinal column, posteriorly, to the middle axillary line, anteriorly.[3] In practising *percussion of the spleen*, the examiner should place his patient upon the right side, or in the semi-prone position, the body being inclined toward the right, in order that the stomach be prevented, so far as possible, by the force of gravity, from becoming interposed between the spleen and the abdominal wall. It is also useful to employ percussion during alternate full inspiration and complete expiration, in order to discover to what extent the lung overlaps the spleen in these opposite phases of the respiratory cycle, and to ascertain the extent of displacement of the organ occasioned by the ascent and the descent of the diaphragm.

It is only in diseased conditions of the spleen that inspection, auscultation, palpation, and aspiration furnish positive information. If the organ be sufficiently enlarged, inspection may show an unusual prominence of the abdominal parietes in the hypochondriac region, or even in the epigastric, the umbilical, the lumbar, the iliac and the hypogastric regions. Pulsation of the spleen, perceptible to the touch, has been noted in cases of free aortic regurgitation. Auscultation may reveal friction sounds due to peri-splenitis, or, possibly, the hydatid thrill, while the palpating fingers encounter a smooth, ovoid tumor, usually hard, smooth, and rounded above, and presenting a notch or depression in its anterior border. In cases of only moderate enlargement palpation may be usefully employed in the following manner: The patient, being on his right side, is instructed to flex his thighs and legs, thus relaxing the abdominal walls, and to alternately inhale and exhale as fully as possible. The examiner meantime places the thumb of his left hand in the left lumbar, and the corresponding fingers in the hypogastric region, and making deep pressure endeavors to grasp the spleen. Percussion, under these circumstances, shows flatness involving the normal splenic site and the other abdominal regions occupied by the tumor. If the patient assume the genu-pectoral position an enlarged spleen will often fall forward, and it may be made to rise on expiration and to descend during inspiration, if adhesions do not prevent it from so doing. Aspiration may be employed as a means of differential diagnosis in cases of fluctuating splenic tumors, as in hydatids and in abscess.

The chief abdominal tumors liable to be mistaken for an enlarged spleen are renal growths involving the left kidney, fæcal accumulations in the splenic flexure of the colon, gastric neoplasms, abscesses in the abdominal walls, or tumors of the pancreas, of the left lobe of the liver, of the omentum and of the ovary.[4]

Tumors of the left kidney may be distinguished from splenic enlargements by the facts that they are more fixed; that, with the exception of movable kidney, they do not follow the respiratory movements of the diaphragm, and that they are not displaced from their original position by changes in the patient's position. The renal tumor will also usually occupy a position posterior to the site of splenic enlargements, and may cause characteristic urinary symptoms.

Fæcal masses in the splenic flexure of the colon may closely simulate splenic tumors, but they are usually of elongated form, their long axis corresponding to the course of the intestine, in which direction they may be spontaneously or artificially displaced. They may, moreover, be indented with the finger, and may then retain the digital impression, owing to their inelastic character. In many cases fæcal tumors may be removed by the judicious and persistent use of purgatives and of laxative enemata.

Malignant gastric growths generally do not occupy the position assumed by splenic tumors, are usually of smaller dimensions, do not readily change their place during respiration or on palpation, and are attended with a familiar train of diagnostic symptoms.

Chronic abscess of the abdominal walls may be distinguished by its superficial character, its traumatic origin, and by the absence of sufficient causes for splenic enlargements. For the differential diagnosis between tumors of the spleen and *pancreatic, hepatic, omental and ovarian enlargements*, of which the first are less frequent than splenic tumors, and the others, from their position and history, are not likely to be confounded with these, the reader is referred to the writer's article on Abdominal Tumors, in this HANDBOOK.

ACUTE SPLENIC TUMOR. *Definition.*—Sudden enlargement of the spleen occurring in various febrile and infectious diseases, and due either to combined congestion and hypertrophy, or, in cases of short duration, to congestion alone. The physiological enlargements of the organ, incident to digestion and to menstruation, are not generally included in the category of splenic tumors, although, strictly speaking, they might be classified under this heading.

Etiology.—This form of splenic tumor occurs with great constancy in some of the infectious diseases, as in typhoid and in typhus fever, relapsing, intermittent and remittent fevers. It is also generally observed in the course of septicæmia, pyæmia, acute yellow atrophy of the liver, acute miliary tuberculosis, erysipelas, puerperal fever, dysentery, splenic fever, scurvy, glanders, ulcerative endocarditis, variola, scarlatina, cerebro-spinal fever, diphtheria and acute follicular tonsillitis. It is sometimes seen in pneumonitis, acute pharyngitis, primary and secondary syphilis, and in acute coryza, gastro-enteritis and rheumatism. Acute splenic tumor may, moreover, be due to sudden occlusion of the portal vein in pyle-thrombosis or pyle-phlebitis, and to traumatism. Congenital acute splenic tumor sometimes occurs in children whose mothers have suffered from malarial fever during their pregnancy.

Pathogeny.—The splenic enlargement is generally explained by the assumption that the micro-organisms which constitute the *materies morbi* in many of these diseases accumulate in the spleen, owing to the filter-like arrangement of its vessels, occasioning congestion and inflammation both mechanically and by the irritating quality of the excrementitious products resulting from their retrograde metabolism. The discovery of numerous micro-organisms in the spleen pulp, after splenic fever and pyæmia, lends probability to this view of the pathogeny of acute splenic tumefactions, which is, however, not yet universally accepted.

Pathological Anatomy.—In those forms of acute splenic tumor which are of very short duration, the only morbid anatomical change is a more or less intense hyperæmia. Should, however, the pathological process, to which the splenic tumor is secondary, be at all protracted, the spleen, besides increasing in size, even to two or three times its normal volume, becomes soft, and sometimes almost diffluent. Its color is reddish-brown, or reddish-blue, and is sometimes mottled gray and red. Peri-splenitis may exist. *On section* the pulp becomes elevated above the cut surface of the capsule. The Malpighian bodies, which are generally not seen, may be plainly discerned in some cases, and are occasionally notably enlarged, particularly in scarlatina.[5] The trabe-

culæ are ordinarily obscured by the swollen pulp. The microscope shows the essential lesion to be either an hyperæmia, in cases of short duration, or an hyperplastic splenitis chiefly affecting the corpuscles of the splenic parenchyma. The interstices of the pulp often contain an abnormally large number of red and white blood-corpuscles, and some cells of varying size, pigmented, or fatty and granular. These inflammatory changes generally undergo rapid resolution after the cessation of the primary disease. In cases of typhoid and relapsing fevers this retrogressive change is, however, often long delayed, and in malarial disease particularly, when the patient suffers from repeated attacks, or the lesions may persist indefinitely, constituting one variety of chronic splenic tumor.

Clinical History.—An acute splenic tumor, of moderate or even of considerable size, may not reveal its presence by any subjective phenomena, or these may be masked by the symptoms of the primary disease. Often, however, the enlargement causes a vague sense of weight and discomfort in the left hypochondrium, with tenderness on pressure, and occasionally even *pain*, which, although ordinarily dull and constant, may, rarely, be sharp and shooting, radiating even into the left arm and leg. In the latter case, the existence of peri-splenitis may be rationally inferred. Rupture of the spleen has been known to occur in typhoid and intermittent fever and in other infectious diseases, but it is extremely rare and is hardly to be anticipated, except as the result of traumatism. If rupture occur, it will almost necessarily prove fatal from hæmorrhage, shock, or peritonitis. It is desirable that statistics be gathered bearing upon the frequency with which, in infectious diseases, acute splenic tumor is developed in anticipation of the characteristic constitutional symptoms. It is to be hoped that the physician of the not distant future may be enabled, having early discovered the approach of infectious diseases by splenic enlargement, to sometimes adopt efficient abortive measures of treatment. Mosler describes a murmur heard over the spleen during the febrile paroxysm of intermittent fever, and holds the opinion that the murmur is due to contraction of the splenic artery in the cold stage of the fever.[6]

Diagnosis.—In a case of splenic tumor, found coincidentally with an acute febrile disease, the only question requiring attention from the differential diagnostician relates to the exclusion of chronic splenic tumor. The previous history, particularly if it embrace records of thorough physical examinations, may here be of great service. Failing this, the disappearance or persistence of the tumor, after defervescence, will furnish the required information.

Prognosis.—This relates, first, to immediate danger from the splenic tumor, and, second, to the liability to the development of chronic splenic tumor as a sequela of the acute. Life is only imperilled, in acute splenic tumor, by the rare occurrence of rupture; while a chronic tumor is not developed, even in malarial fevers, provided that proper and persistent antiperiodic treatment be adopted.

Treatment.—Therapeutic measures especially directed to the splenic tumor are rarely required. The primary disease takes precedence of this, its local manifestation, and treatment adapted to the cure of this malady will effect all the improvement in the condition of the spleen that can be expected from internal medication. Should the pain be excessive or lancinating, local revulsive applications, as dry cups and iodine, or hot fomentations, together with anodynes internally administered, will generally fulfil the indications for treatment.

Chronic Splenic Tumor. *Etiology.* — The chief causes of chronic splenic tumor are malarial fever or the malarial cachexia, leucocythæmia, and pseudo-leucocythæmia. This form of tumor is also often found in those who have long resided in malarial districts, even although they have never suffered from any form of malarial disease. Of less importance, as etiological agents, are all the causes of mechanical obstruction to the portal system, of which the splenic vein is an important radicle. In this category belong hepatic cirrhosis, pyle-phlebitis, abdominal neoplasms pressing on the portal vein, thoracic tumors obstructing the inferior *vena cava*, mitral and tricuspid valvular lesions, interstitial pneumonitis or fibroid phthisis, chronic pleuritis with retraction or with great effusion, and pulmonary emphysema. Many of these conditions are, however, often found without a coexistent splenic tumor, and even when the spleen is abnormally small from fibroid contraction or from simple atrophy. Syphilis is said to occasionally produce this lesion independently of its own characteristic form of splenic tumor, and, in rare instances, no cause for the enlargement can be ascertained.

Morbid Anatomy.—The size of the spleen is augmented sometimes to an enormous extent. The organ has been known to weigh fifteen or sixteen times as much as in the normal state.[7] Its shape remains unchanged; its consistency is greatly increased, and its color is, as a rule, dark red or brownish-black, but it may be normal or mottled. The capsule is thickened and may be adherent to surrounding viscera, as the result of antecedent peri-splenitis. On section the cut surface is seen to be smooth and indurated. The glomeruli and trabeculæ may be either almost invisible or very distinct. The microscope shows the lesion to consist in chronic hypertrophic splenitis, involving especially the trabeculæ, but often both these and the splenic cells. Pigmentation of the cells in the pulp, of the Malpighian corpuscles, or of the trabeculæ is not uncommon. For the pathological anatomy of leucocythæmia and of pseudo-leucocythæmia, the reader is referred to the articles in this Handbook treating of these subjects.

Clinical History.—The subjective symptoms are essentially the same as those of acute splenic tumor, viz., slight pain, tension, or fulness, and a dragging sensation in the left hypochondrium, sometimes notably increased by the assumption of the lateral decubitus. In some cases there may be splenic ectopia. We may have certain symptoms due to the pressure of the tumor upon adjacent viscera, such as cardiac arhythmia, gastric disturbances, obstruction of the colon, and chronic ulcer of the leg from interference with the blood-current in the ascending venous channels. Gerhardt described a pulsating splenic tumor presenting a double murmur in a case of aortic insufficiency.[8] All the above symptoms are insignificant when compared with those due to the diseases causing the splenic hypertrophy.

Diagnosis.—For the chief differential points between chronic splenic tumor and other abdominal tumors, the reader is referred to the introductory remarks on the differential diagnosis, and for a fuller exposition of the symptoms and signs characteristic of other splenic tumors likely to be mistaken for this form of tumefaction he may consult the remarks made in this article regarding the other causes of splenic enlargement. Acute splenic tumor is easily distinguished by its brief duration, waxy spleen by the pre-existence of suppurative diseases, syphilitic degeneration by the history of a constitutional taint, and hydatids by fluctuation, thrill, and aspiration. If the chronic splenic tumor be due to malaria, the peculiar cachexia of chronic paludism may be present and pigment particles be found in the blood; if to leucocythæmia, the blood will present an excess of white corpuscles; if to Hodgkin's disease, the lymph-glands will probably be enlarged.

Prognosis.—The exact share borne in the lethal issue of any disease of which chronic splenic tumor is a subordinate clinical feature, by the pathological condition of this organ can, with our present knowledge, only be conjectured. If vital organs are affected by pressure, the influence of the tumor can but be prejudicial to the general strength. We can only repeat that the prognosis, as to life, will depend on the primary disease, and *not* on the secondary splenic condition. If new connective tissue has been formed in the spleen or in its capsule, a complete resolution is, of course, not to be expected.

Treatment.—In chronic splenic tumor from malaria, quinine and arsenic are useful, and removal from a malarial district is to be strongly recommended. In any

form of chronic splenic tumor, electricity and ergot may be tentatively employed, the latter perhaps best, hypodermatically over the region of the spleen. Da Costa reports a case of splenic leucocythæmia successfully treated with ergotin thus administered.[9] Ice-bags continuously employed for long periods may render considerable service, probably in the same way as ergot and electricity, *i.e.*, by stimulation of the intrinsic splenic muscular fibres. Counter-irritation, by means of tincture of iodine carefully employed, has been productive of good results. Occasional depletion of the portal system by mild cathartics is to be recommended whenever the chronic splenic tumor is due to portal obstruction. If anæmia and asthenia are present, ferruginous tonics and roborant measures are, naturally, indicated. Extirpation of the spleen may be considered, as a last resort, when the tumor is so large as to produce injurious pressure on important organs, or is progressively increasing in size. Crédé believes that the operation is justifiable.[10] Collier found that out of twenty-nine operations tabulated by him sixteen were performed for the removal of leucocythæmic spleens and were all fatal, while eight of the remaining thirteen patients made good recoveries.[11]

PERI-SPLENITIS. *Definition.*—Acute or chronic, localized or diffuse inflammation of the capsule and of the peritoneal investment of the spleen.

Etiology.—Peri-splenitis is caused by great over-distention of the capsule, as in cases of malarial fever and of other infectious diseases, by extension to the capsule of interstitial splenitis, by involvement of the capsule in inflammations of neighboring tissues, as in perinephritis, in gastric ulcer or cancer, and in general or localized peritonitis. Chronic peri-splenitis often occurs with chronic splenic tumor. It may be a sequel of acute capsulitis, or be coincident with chronic peritonitis. Some writers maintain that peri-splenitis may be caused by chronic alcoholism and by syphilis.

Pathological Anatomy.—In acute peri-splenitis fibrin and pus are formed upon the peritoneal coating of the capsule. In chronic peri-splenitis the capsule is more or less thickened from the development of new connective tissue. It may be adherent, through the medium of this new tissue, to adjacent organs. Its color is lighter than normal, and the new tissue, particularly in localized peri-splenitis, is dense and of cartilaginous firmness. It may have undergone calcification. The new connective tissue sometimes assumes the form of nodules or of papillary outgrowths. In peri-splenitis of apparently syphilitic origin the connective tissue may form small, opaque, whitish plates or disks.

Clinical History.—In some cases of malarial and other fevers a friction-sound is heard over the enlarged spleen during the respiratory movements. This is the first, and in mild cases the only, symptom of peri-splenitis. Severer cases will be attended by the lancinating pain which is characteristic of local peritoneal inflammation, which is aggravated by movements of the diaphragm, or by changes in position, and which may radiate into the left arm or thigh. Beyond this there will be no symptoms or signs until after the development of adhesions between the spleen and neighboring organs, when the spleen may remain immobile during respiration and present certain irregularities and prominences to the palpating fingers. Adhesions may be assumed to exist if there is no enlargement of the spleen during acute infectious diseases, or if splenic dulness persists after the occurrence of intestinal perforation.

Diagnosis.—Peri-splenitis is to be distinguished from perihepatitis over the left lobe of the liver, and from the first stage of pleuritis, particularly of diaphragmatic pleuritis. The differentiation is often very difficult, and is largely based upon the clinical history of these diseases. Thus the effusion of pleurisy, and the larger area over which hepatic friction-sounds are audible will somewhat assist the diagnostician.

Prognosis.—This is invariably favorable in simple cases, since peri-splenitis leaves no after-effect, unless it be pain from traction of an enlarged spleen upon newly formed peritoneal adhesions.

Treatment.—This will embrace measures for the relief of the pain in the earliest stage of the inflammation, such as the application of hot fomentations, of revulsives, and of counter-irritants. For severe pain anodynes may be administered by mouth or hypodermatically. The pain due to traction of the spleen upon peritoneal bands and adhesions may be mitigated by the use of a belt or girdle for the support of the enlarged organ.

INFARCTION. *Etiology.*—Splenic infarction is due to embolism of the splenic arterioles. These vessels belong to the class of arteries known as end-arteries, *i.e.*, they do not terminate in anastomosing capillaries, but in intercellular vascular spaces. The most favorable conditions for the occurrence of hæmorrhagic infarction are afforded by this vascular arrangement and by the absence of valves in the splenic vein, which allows the free regurgitation of venous blood. The emboli causing obstruction of these arteries usually come from the left heart or the aorta, but in pyæmic cases they may proceed from the lungs, or, possibly, from even more remote parts of the body. They consist, either of vegetations from the endocardium, of atheromatous particles, of fibrin detached from thrombi, or of colonies of micro-organisms surrounded by fibrin. Splenic infarctions may be classified as simple and mycotic, in accordance with the character of the emboli which cause them.

Pathological Anatomy.—Simple splenic infarctions are wedge-shaped, corresponding to the conical area supplied by the obstructed arteries, and generally near the surface. The apex of the wedge is directed toward the hilum, while the base often projects above the surface. There may be but one infarction, or there may be many infarctions. The size of the infarction varies ordinarily from that of a pea to that of an egg, but it may be much larger, owing to the coalescence of adjacent areas of infarction. If such a coalescence be established, the characteristic wedge-shaped or conical form may be no longer preserved. On section the infarction is found to be either hæmorrhagic, white, or mixed. In recent cases it is usually firm, whitish in the centre, and red at the periphery. Localized peri-splenitis may be found over the base of the infarction. In cases of longer standing the color is yellowish-white, from pigment absorption and from fatty degeneration of the cells. In some cases an infarction may soften and be absorbed, leaving a cicatrix. Again, it may successively undergo fatty, cheesy, and calcareous degeneration. Rarely it suppurates. The microscope shows that the hæmorrhagic infarction is made up of red blood-corpuscles and of compressed splenic tissues, while in the white infarction the cells are in a condition of coagulation necrosis. Mycotic infarctions are surrounded very early by zones of inflammation, due to the irritation of the micrococci, and the pathological changes soon pass into those of splenic abscess (*quod vide*).

Clinical History.—Simple splenic infarctions give rise to no symptoms, unless from accidental causes they occasion acute splenitis and perisplenitis, diseases described in this article under those headings. They are therefore devoid of importance, inaccessible to diagnosis, and claim no treatment, often being found at autopsies of persons in whom their existence was not suspected. The clinical history and the treatment of mycotic infarctions merges into that of metastatic splenic abscess, to be presently described.

ABSCESS. *Etiology.*—There are two chief varieties of splenic abscess, namely, those due to traumatism, to extension of inflammation from neighboring viscera, or to simple embolism, which are quite rare, and those caused by septic embolism, which are frequent. The former class of abscesses is caused by wounds or contusions of the spleen, by the extension of inflammation from the stomach in cases of gastric ulcer or cancer, by the presense of neoplasms, or, very infrequently, by suppuration of a simple infarction. An abscess of this kind may complicate typhoid, relapsing, or intermittent fever, and sometimes may be developed without known cause. The second variety of abscess is the result of mycotic endocarditis or of pyæmia.

Pathological Anatomy.—Abscesses of the former variety, which, in contradistinction from those due to septic embolism, may be designated as *simple abscesses*, are generally, although not necessarily, larger than the latter. They may lead to the destruction of the entire parenchyma of the organ, the capsule becoming distended with pus and disintegrated splenic tissue. On section the trabeculæ may be seen traversing the diffluent mass, or they, too, may have been broken down. The capsule is indurated, thickened, often adherent to other organs or tissues, and occasionally destroyed by the advance of the abscess toward the surface of the spleen. Smaller simple abscesses may become encapsulated, and, eventually, be reabsorbed, leaving a cicatrix, or they may undergo caseous and calcareous degeneration. Splenic abscesses in any of the above stages, latent as regards symptoms and signs during life, may be discovered at autopsies held upon the victims of various diseases. Large abscesses may rupture and discharge their contents either into the peritoneal cavity, the colon, the pleural cavity, upon the cutaneous surface, into the renal pelvis, or into the retro-peritoneal tissues.

Septic abscesses are ordinarily of small size, because the diseases to which they owe their origin are so often rapidly fatal. Their form may be that of a splenic infarction, from which they often develop, namely, wedge-shaped, the base being directed toward the surface, or it may be very irregular, when the area involved in the infarction has undergone complete necrosis. On section one finds a central mass, which the microscope shows to be made up of leucocytes, granular amorphous *detritus*, and micrococci, surrounded by coagulated fibrin and bordered by a dark congested zone of otherwise normal tissue.

Clinical History.—The symptomatology of splenic abscess is not well made out, on account of the great rarity of the disease. The symptoms of abscesses other than mycotic, as described by those authors who have observed them, are merely those of suppuration in any tissue, and collectively known as hectic fever, together with pain and tenderness in the left hypochondrium, dependent upon peri-splenitis and upon peritoneal adhesions. The pain is said to have radiated, in some cases, into the left shoulder. Rupture of the abscess into the peritoneum causes fatal peritonitis; rupture into the pleura and the bronchi, pleuritis, bronchitis and pneumonitis. In a case of supposed splenic abscess, treated by the writer, pus was abundantly discharged by the bronchial tubes and recovery took place. Rupture into the stomach or into the intestine would be followed by the vomiting or by the dejection of pus and blood, and rupture into the kidney by pyuria and hæmaturia. The physical signs, if the abscess be of considerable size, are those of splenic enlargement with possible fluctuation; but in small abscesses, terminating by caseation and calcification, these signs would probably be absent.

The symptoms and signs of mycotic abscess are usually negative, or are completely masked by those of the coexisting endocarditis or pyæmia. They rarely occasion tenderness, pain, or perceptible splenic enlargement, except in chronic pyæmia, when they may, by the coalescence of several small foci of suppuration, become large and fluctuating. Should the capsule and the peritoneum covering the spleen become involved, there may be considerable lancinating pain and marked tenderness.

Diagnosis.—Simple splenic abscess, large enough to present physical signs, might be mistaken for perinephritis, for pyelo-nephrosis, for sacculated empyema occupying the most dependent part of the left pleural cavity and for hydatids of the spleen. The exclusion of all these diseases but the last one might prove almost impossible, except by exploratory incisions. Some assistance in making a diagnosis might be derived from the fact that a splenic abscess which had not caused adhesions of the spleen would descend on inspiration, which a perinephritic, nephritic, or pleural abscess would not do. Hydatids of the spleen would furnish a characteristic fluid on aspiration. Carcinoma of the cardiac extremity of the stomach and pancreatic tumors may also be mistaken for splenic abscess. The existence of mycotic splenic abscess can generally only be suspected when local signs are developed in pyæmic cases, but the large abscesses of chronic blood-poisoning are more easily diagnosticated.

Prognosis.—Mycotic abscess is not, in itself, fatal, but the pyæmia of which it is a subordinate feature offers a grave prognosis. Simple abscesses are usually fatal, either by rupture or by gradual exhaustion. The prognosis is, however, by no means hopeless, since rupture onto the surface, or in almost any direction save that of the peritoneum, may be followed by recovery.

Treatment.—In suspected cases of beginning simple abscess, active prophylactic treatment must at once be adopted. This treatment will embrace saline laxatives, local abstractions of blood and ice-bags kept constantly applied. Bartholow recommends warm fomentations, turpentine stupes and hot poultices, besides the free administration of quinine.[12] Fluctuating abscesses, simple or pyæmic, should be evacuated with strict antiseptic precautions. The smaller mycotic abscesses are not amenable to treatment.

WAXY SPLEEN. *Etiology.*—Amyloid disease of the spleen occurs under the same circumstances which occasion waxy changes in other organs, namely, during protracted suppurative diseases, particularly in those affecting bone or pulmonary tissue, and in syphilis. Malarial disease is sometimes included in this category of causes, and, in rare cases, no cause can be discovered. This disease of the spleen is rarely encountered except in cases presenting waxy changes in the liver, the kidney, and the intestine.

Pathological Anatomy.—There are two varieties of amyloid spleen. The former is known as the "sago spleen," and the latter as diffuse waxy disease of the spleen. In the former variety the organ is sometimes enlarged, and is sometimes not so. In the latter, the spleen is enlarged, tenacious, and indurated, its capsule being tense and glistening and its edges blunt or rounded. On section the "sago spleen" presents grayish, round, or oval translucent bodies scattered through splenic tissue, which may either be otherwise healthy, or may, also, be involved in the same pathological change. The above-mentioned granules correspond to the Malpighian bodies, and vary in size from about one twenty-fifth to about one-eighth of an inch. In the diffuse variety of amyloid spleen the degenerative change is generally held to have invaded all the splenic tissues, but chiefly the pulp and the trabeculæ. On section the cut surface is waxy and more or less translucent, varying in color from a grayish-red to a dark grayish-brown. It is probable that the waxy change occurs first in the walls of the arteries, in both varieties, and subsequently involves the other structures. The tests for the waxy material are as follows: If Lugol's solution, *i.e.*, the compound solution of iodine, be applied to the cut splenic surface, those tissues which have undergone the amyloid change will assume a mahogany color, the normal tissues merely taking on a yellowish tint. A still more delicate test-fluid is a solution of methyl violet, which imparts a red color to amyloid material, the normal splenic tissues becoming distinctly blue.

Clinical History.—No symptoms can be directly referred to waxy changes in the spleen, unless the organ has become so much enlarged as to cause a feeling of fulness, of weight, or of traction. The other symptoms observed, in any case, will almost invariably be due to the amyloid disease in other organs, as diarrhœa in intestinal disease, and characteristic urinary symptoms in amyloid kidney. There is usually profound anæmia, with all its symptoms, and hæmorrhages from mucous surfaces may occur. On physical examination the spleen is found enlarged and hardened, but it is smooth, retains its shape, is not adherent to any other organ, and is movable.

Diagnosis.—This must ordinarily be based upon the concomitant symptoms of waxy change in other organs, *i.e.*, in the liver, the kidneys, and the intestine, together with the physical signs and the early history of suppuration or of syphilis. Chronic splenic tumor might be er-

roneously considered as waxy spleen, but the history of antecedent malaria, and the microscopical examination of the blood, would exclude both "ague-cake" and leucocythæmia; while the absence of general glandular enlargements would disprove the existence of pseudo-leucocythæmia.

Prognosis.—This is bad, not from the amyloid disease of the spleen, but from the existence of the same change in other and vital organs.

Treatment.—The treatment is almost wholly prophylactic, embracing removal of all possible foci of suppuration and the eradication of the syphilitic cachexia. It is possible that the waxy disease, if not far advanced, may disappear, but it is uncertain whether there be therapeutic means of hastening the resolution.

SPLENIC NEOPLASMS. 1. SYPHILIS.—Splenic syphilis may be congenital or acquired, circumscribed or diffuse. The acquired form is not very common, while congenital splenic lesions are found in perhaps one-fourth or one-third of all cases of hereditary syphilis.[13]

Pathological Anatomy.—In the early stages of syphilis the spleen may be enlarged by congestion, and, perhaps, by moderate hyperplasia, thus constituting one variety of acute splenic tumor, as in other infectious febrile diseases. We have already stated that lardaceous splenic disease, as well as diffuse interstitial hyperplasia, is sometimes caused by syphilis. As these lesions have been described under their respective titles, it now only remains to mention the other pathological change wrought in the splenic tissues by the syphilitic virus, viz., the so-called gummata. These gummata are generally small, some of them being no larger than a grain of millet-seed, others as large as a small bean or lentil. They are, ordinarily, not numerous, and may be either distinctly circumscribed or somewhat diffused. They are usually situated near the surface of the spleen. Syphilomata are, at first, reddish-white, assuming, when less recent, a yellowish tint, and becoming dry, tough, and almost cheesy.[14]

Clinical History.—This is negative. The diagnosis can hardly be made with any degree of certainty. The existence of gummata may be, at most, suspected, if splenic tumefaction, with peri-splenitis, develops during the demonstrated growth of syphilomata in other organs, waxy disease having been excluded.

Treatment.—Acute splenic tumor, due to syphilis, may be reduced by the speedy adoption of specific treatment. Splenic gummata are often readily amenable to treatment with large doses of potassium iodide or to the mixed treatment, while diffuse syphilomata are uninfluenced by any therapeutic measures.

2. TUBERCLE.—Acute splenic tumor, without tuberculous deposits, occurs during the progress of acute tuberculosis. Splenic tubercles, proper, are apparently either always secondary to tuberculous growths in other organs, or appear, simultaneously with widely disseminated tuberculous growths, during the course of acute miliary tuberculosis. In the former case the tubercles are often not very numerous and are visible to the naked eye, varying in size from that of a millet-seed to that of a pea, the largest ones being doubtless composed of several smaller aggregated tubercles. These growths are sometimes called solitary tubercles. They are, at first, grayish and translucent, assuming later a yellowish or cheesy appearance. Their histological features are the same as in tubercles of other organs, and they generally contain numerous bacilli. They are found in the trabeculæ, the capsule, the Malpighian bodies, in the pulp and in the walls of the small arteries[15] (*vide* article Tubercle, in this HANDBOOK).

The splenic tubercles developed in acute miliary tuberculosis are often invisible to the naked eye, and are distinguished with difficulty even by the microscope, since their structure, at an early stage, closely resembles that of the splenic pulp. Tubercles of the spleen are alike devoid of interest for the clinician, the diagnostician, and the therapeutist.

3. MALIGNANT TUMORS, CARCINOMA AND SARCOMA.—These new-growths are hardly ever primary, but usually develop secondarily to other malignant tumors, either by metastasis or by direct extension from a primary neoplasm in the stomach, the liver, the pancreas, and the mesenteric or retro-peritoneal glands. Jeannel states that only seven primary splenic cancers have been reported.[16] Splenic carcinomata are ordinarily of the medullary variety and are often pigmented. These malignant tumors grow with great rapidity, and, if superficially located, may be discovered by palpation. As a rule, they escape detection. Their presence may be inferred if enlargement of the spleen be coincident with the development of malignant growths in other, and particularly in abdominal, organs. These tumors are of little clinical significance, and affect the prognosis unfavorably only in that they give evidence of a more or less wide distribution of the carcinomatous or sarcomatous disease.

4. ECHINOCOCCUS.—This is one of the rarest of splenic tumors. It develops, usually, simultaneously with hydatids in other abdominal organs, particularly with hepatic echinococcus. The disease attacks both sexes with approximately equal frequency, and is chiefly found in middle-aged persons.

The etiology is the same as that of hydatid disease, wherever located, the cause of the disorder being the entrance of the scolices of the tænia echinococcus into, and their establishment in the spleen.

It has been asserted that echinococci of the spleen are generally secondary to other hydatid tumors of the abdominal organs, but this question is not definitely settled.

Morbid Anatomy.—As a rule, there is but one mother-cyst, within which numerous daughter-cysts develop, but there may be a large number of mother-cysts. The hydatids are ordinarily developed from the capsule of the spleen or from its serous investment, but they may originate in the spleen pulp, which, in either case, is destroyed by the pressure of the tumor. The cyst usually increases slowly in size, if uninfluenced by treatment, and, after months or years, finally ruptures into the peritoneum, into some hollow abdominal viscus, as the alimentary canal, into some thoracic cavity, as the pleura or the pericardium, or onto the cutaneous surface. In more favorable cases the cyst may remain stationary in size, occasioning no noteworthy splenic lesion. Suppuration of the cyst may occur, or the cyst may undergo calcareous degeneration, remaining encapsulated and innocuous.

Clinical History.—Small, and sometimes even large hydatid cysts may give rise to no symptoms or physical signs. When, however, a certain size is attained, the patient may complain of weight, tension, and pain, either constant or intermittent, over the region of the spleen, which organ, on physical examination, may be found enlarged in various directions and displacing abdominal and thoracic viscera. Emesis may thus be occasioned by pressure upon the stomach, and obstipation by obstruction of the large intestine. If peri-splenitis coexists, a friction, sound may be perceived. The hydatid thrill is occasionally present, as well as fluctuation. If the cyst ruptures, the symptoms will vary with the organ into which the discharge occurs, and need not be here enumerated, since they are almost identical with those occasioned by the rupture into these various viscera of a splenic abscess, and are described under that caption. Suppuration of the cysts will occasion the familiar symptoms of hectic fever.

Diagnosis.—The establishment of a differential diagnosis involves the exclusion of abscess and of solid splenic tumors. Aspiration will distinguish between these and hydatids, if the characteristic saline fluid, containing hooklets, be obtained. Fluctuation will, when present, exclude solid tumors, and the hydatid thrill is pathognomonic. Small or encapsulated hydatids will elude diagnosis, and it may be impossible to distinguish between simple splenic abscess and suppuration of an hydatid cyst.

Prognosis.—This is very bad, but not hopeless. Rupture does not necessarily occur, but when it does happen

is almost always fatal. The growth of the cyst may be spontaneously arrested, and calcification sometimes renders the tumors harmless, while judicious treatment may materially assist nature in effecting a cure.

Treatment.—The treatment to which the majority of writers lend the weight of their authority consists in the partial evacuation of the cyst, or cysts, by which proceeding the death of the parasites is brought about, and absorption, atrophy, and calcareous degeneration of the remaining contents of the cyst are favored. The evacuation of the fluid should be accomplished by means of a very small trocar, and it is advisable to excite localized adhesions between the cyst and the abdominal wall by means of caustics before aspiration is attempted. The operation and the whole after-treatment should be conducted in accordance with the most approved antiseptic principles. Should suppuration of the sac occur spontaneously, or as a result of aspiration and the ingress of air, a free opening must be made and efficient drainage afforded.

5. Miscellaneous Tumors.—Other and rarer splenic tumors than those above described are fibromata, angiomata, dermoid, and other cysts, besides calcified cysts containing the pentastomum denticulatum. All these new-growths are generally of so small size as to be quite devoid of clinical interest.

Rupture of the Spleen. *Etiology.*—Rupture of the spleen may be either spontaneous or traumatic, but trifling injuries may so often provoke apparently spontaneous lacerations that a sharp dividing line cannot be drawn between these two varieties. The so-called spontaneous ruptures generally occur in cases of acute splenic tumor complicating typhus, typhoid, and intermittent fevers, or other infectious diseases, as well as in abscess, aneurism, varices, or hydatids of the spleen. Traumatic rupture results from violence direct, or rarely indirect, exerted, in almost all cases, upon an enlarged and softened organ. Falls, kicks, and blows, fracture of the ribs, and penetrating wounds are the most common traumatic causes, while acts of emesis, convulsions, and the contortions of parturition have been noted as rarer causative events.

Pathological Anatomy.—Spontaneous rupture usually occurs at a single point, while traumatic rupture may cause lacerations in several different places. Autopsies, in cases of rupture, reveal the diseased condition of the organ which predisposed to rupture, and the presence of blood and *débris* of the splenic tissues in that organ or cavity into which these materials have been discharged. If the patient's life has been sufficiently prolonged, there will be found evidences of the secondary disease due to the rupture, as of peritonitis, pleuritis, or pericarditis. In distinctly traumatic cases there may be contusions or other visible surface evidences of violence, or these may be wanting.

Clinical History.—The symptoms are those of rupture of any vital abdominal organ, and they particularly resemble those following perforation of the bowel, with or without hæmorrhage into the peritoneal cavity. The leading symptoms are a feeling as if some vital organ had suddenly given way, and violent pain over the spleen, soon followed by acute anæmia and rapidly increasing asthenia. Death, either immediately or after a few hours, is the almost inevitable result. Recovery may, however, take place, if the rupture is slight and does not occur into a serous cavity. The treatment, which is usually unavailing, embraces absolute quietude, applications of ice to the abdomen, and generous doses of morphine, hypodermatically administered.

Ectopia and Malformations.—Cases of splenic ectopia, or floating spleen, are comparatively rare. They may result from failure of the suspensory ligament and of the gastro-splenic omentum to retain the organ in place. Such failure may be due to congenital relaxation of the ligaments, to their abnormal length, to traction upon them of an enlarged spleen, or to traction upon the spleen exerted by the contraction of newly formed peritoneal bands. Atrophy of an originally normal or of an hypertrophied spleen may be caused by torsion or compression of the splenic vessels incident to the organ's displacement. Ectopia is to be differentiated from simple enlargement by the aid of physical exploration, and the spleen, having been restored to its normal position by careful manipulations, is to be retained there, if possible, by proper bandages or by abdominal supporters.

The spleen may be displaced, either upward or downward, by abdominal or thoracic diseases of such a character as to forcibly press upon the organ. Among such diseases are to be mentioned tumors, ascites, tympanites, emphysema, pleuritic effusions, pneumothorax and spinal curvatures. Lifting great weights and paroxysms of coughing may act as exciting causes of these displacements, which, in turn, cause various pressure symptoms, among which are vesical and rectal tenesmus, paresis of the lower extremities, emesis, and constipation. The spleen may sometimes escape into a hernial sac, either abdominal or thoracic, and it may, rarely, be found on the right side, in cases of visceral transposition.

Two spleens, either of the same size or of different sizes, have been found in the same subject, and small accessory spleens, of various shapes, are often seen. The spleen may, in very rare cases, be congenitally absent in persons whose other organs are all present, and acephalous monsters have sometimes rudimentary spleens, or no spleens whatever. *William H. Flint.*

SPLINTS. The study of splints and methods of splinting is a very interesting one, both to the practical surgeon and to the medical historian.

Ingenuity—and too often misapplied ingenuity—has been expended lavishly in devising splints of the most curious and complicated character, intended to fulfil a number of different indications; splints elaborately carved and often based on false anatomical principles; splints capable of adapting themselves—in a measure—to adults or to children; splints that have been expected to supplement and improve upon the surgeon's faulty work in reduction of fracture, and which have, accordingly, failed of their purpose.

The shops are filled with almost innumerable varieties of splints, devised for the cure of every conceivable fracture. Especially numerous are those for fractures of the femur and of the lower end of the radius. If it is true—which I do not allege—that no obstetrician considers himself eminent in his specialty until he has devised some modification of the obstetric forceps which shall bear his name, it is much more true that almost every surgeon who has written a book—and many who have not—invents some special splint.

It is undeniable that some of the splints stand for a principle, and deserve permanent recognition. The vast majority, however, are relegated by the succeeding generations into oblivion with their authors. This fact is strikingly impressed upon the reader of the surgical works of the last century and the early decades of the present. Here, as in regard to other therapeutic agencies, the pendulum of medical opinion has swung at times from extreme to extreme.

John Bell declared the appliances for treating fracture in his day to be "instruments of torture more terrible

than those used by the Inquisition for that purpose," and substituted therefor much simpler means. Such complicated engines, intended to war against deformity, are not without their types at the present time.

Looking at the other extreme of opinion, we find that at times certain reputable, but misguided, surgeons have actually advocated the treatment of many or all fractures of limbs with no splint save a roller bandage! And others have even done away with this, preferring absolutely nothing. Such absurdities as these are probably the natural revulsion following the contemplation of limbs permanently deformed from splints improperly devised and unskilfully applied.

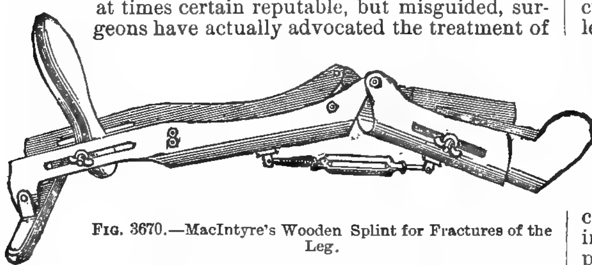

FIG. 3670.—MacIntyre's Wooden Splint for Fractures of the Leg.

Those surgeons who are pre-eminently successful with their fracture cases are not necessarily the ones who have the largest armamentarium of ready-made splints, of myriad shapes and sizes, wherefrom to select for the treatment of any given case. In fact the reverse is often true, and the greatest surgeon possesses few or no stock-splints; but, from splint materials nearest at hand, or readily obtained, makes at short notice for each case a separate and differing splint; one that shall vary with the infinite variety of individual requirements, and which is therefore apt to be better than the ready-made article.

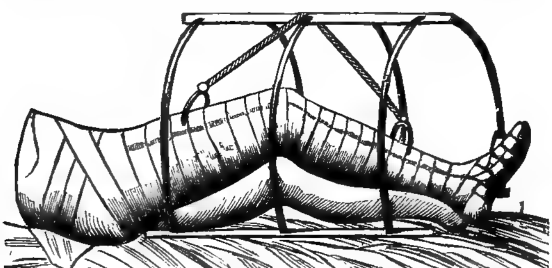

FIG. 3671.—Suspension of the Leg from a Wire Cage.

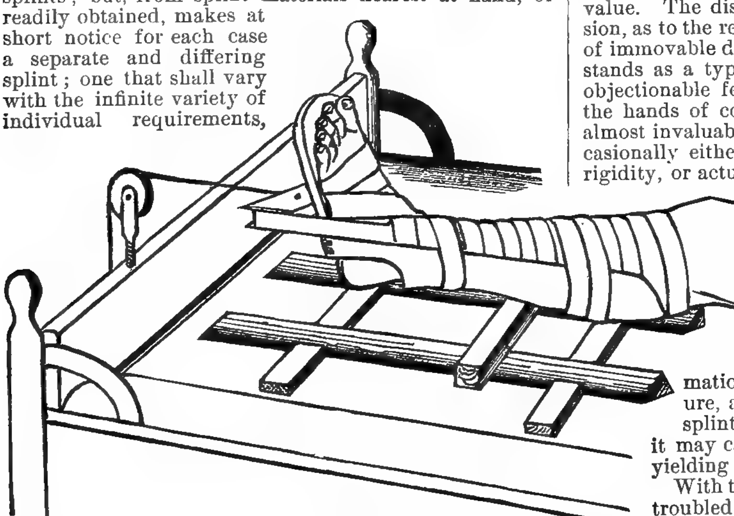

FIG. 3672.—Volkmann's Sliding Leg-rest.

To effect this, a certain degree of deftness and ingenuity is necessary; but this is true of all branches of surgery. And the man who is lacking in this essential will do wisely to choose for his field another department of medicine.

In this article will be discussed mainly the materials used in splinting and the modes of application. Only incidentally are appliances peculiar to some special bone-lesion named, and these are more appropriately studied in conjunction with the phenomena, subjective and objective, which call for their application. Accordingly, the reader is referred for such information to the appropriate headings, as Fractures, Pott's Disease, etc.

Splints are usually divided, for convenience of classification, into two broad groups: the rigid and the plastic. The latter are those composed of substances capable of being made to assume a soft and pliant condition, and subsequently of hardening and maintaining the shape into which they have been modelled. The plastic splints have been in turn subdivided into movable and immovable, which classification seems to the writer an utterly useless one, inasmuch as each and all members of the "immovable" plastic group can at will be so fashioned as to become easily capable of removal.

Not as to *substance*, but as to *method* of splinting, the division *immovable splints* becomes of some practical value. The discussion is not yet ended, in the profession, as to the relative value, in acute injuries, of the class of immovable dressings of which that made of gypsum stands as a type. They have certain advantages; their objectionable features are also now well recognized. In the hands of competent and experienced men they are almost invaluable at times. In other hands they are occasionally either inefficient as a means of maintaining rigidity, or actually dangerous to life or limb. Besides a modicum of experience in the technique of their application, it is essential to the well-being of the patient that the surgeon should recognize certain fixed limitations to their employment. An immovable splint should never be applied to a limb immediately upon the receipt of the injury, or within a few hours thereafter. Considerable inflammation and swelling inevitably follow the fracture, and continue for several days; and as the splint under consideration encircles the limb, it may cause agonizing pain by opposing an unyielding barrier to this swelling.

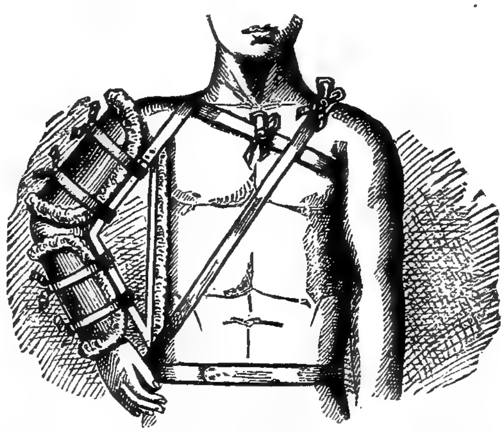

FIG. 3673.—Adaptation of the Double-inclined Plane to the Upper Extremity.

With the ordinary removable splints a patient so troubled could easily free himself. Not so in this case; and if the surgeon be a country practitioner, and hardly able to call again soon, the outcome is occasionally most deplorable. From obstructed circulation gangrene of the point of greatest pressure, or even of the entire extremity, may supervene. This result is, fortunately, rare, but as a danger it must be borne in mind.

Should the patient with fracture be seen first at a period when the inflammation and consequent swelling are at their height, it would probably be wise to wait and not attempt reduction then, unless the fragments be in a decidedly bad relation to each other. But certainly, if splinting be attempted, here is another counter-indication to the use of the immovable method. Upon the subsidence of the congestion the limb will quickly resume its normal size, and a splint closely fitting the limb yesterday may to-morrow be so loose as to aid little in immobilization. The surgeon will consequently have either to cut out a longitudinal strip of the splint, and then by bandage or straps narrow it transversely, or what is probably better and simpler, to remove it and make a new one; either expedient being more annoying and tedious to the attendant than the application of some simple, temporary, removable splint.

It cannot be gainsaid that it is a most desirable thing to have a fractured member freely exposed to the surgeon's eye; and that this is impossible by the immovable method is a strong objection to it. If a strip be cut out, as just mentioned, then we cease to be discussing *immovable* splints, for such a splint can easily be sprung off by the patient himself.

In recent years even the time-honored roller-bandage, wherewith the limb is to be swathed from the digit-tips to above the splint-top, has often been discarded, and wisely. A properly applied splint should rarely cause much circulatory obstruction; and it is well for the surgeon, at least early in bad cases, to be able to watch the whole length of the limb.

The proper time, then, for the application of an immovable splint is after the swelling has completely disappeared, and not before. Even now the limb must unavoidably atrophy somewhat from disuse, so that what was originally a closely fitting jacket will become less so; but this may not now interfere greatly with its practical usefulness.

It is greatly to be desired that a patient shall not be confined to his bed, or even to his room, when avoidable; and in certain fractures of the lower extremity the immovable splint gives us a means, probably better than any other, of permitting locomotion while yet the bone is knitting, with safety to the case.

We may name, among the rigid, non-plastic, splint materials in more or less common use, the following: Wood, tin, sheet zinc, telegraph wire, wire gauze, glass splints.

Besides these, there are many substances used, in temporary or field work, in the absence of more usual means, as plaited unbroken straw, bundles of rushes or stout grass, small fagots of twigs. In fact, the list is almost limitless.

Belonging to a somewhat plastic group are the

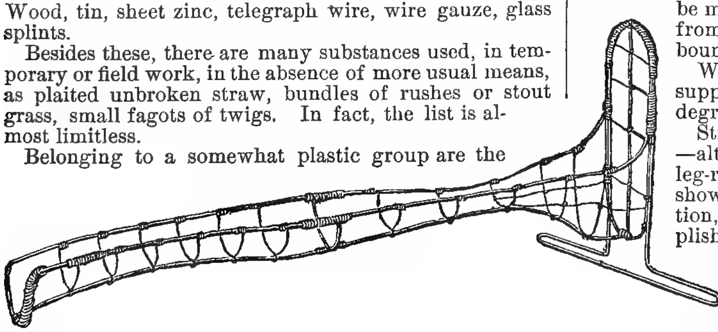

FIG. 3675.—Wire Leg-splint, with Foot-piece and Horizontal Rest.

following: Pasteboard, felt, leather, fresh bark, vulcanized rubber, celluloid, veneering.

Substances of an entirely plastic nature, which are sometimes employed: Plaster-of-Paris, silicates, gutta-percha, paraffine, stearine, starch, dextrine, chalk and gum, glue, glue and zinc oxide, tripolith, clay, shellac cloth or paper, collodion cloth or paper, adhesive plaster.

Among the rigid splint-materials wood is most used. Any thin board will do, preferably one splitting and working easily. A piece of pine shingle will often serve our purpose excellently, where a simple straight splint is required. This must be cut of the desired shape, and then properly padded on the side next the skin. The padding is not to be left loose, but is to be bandaged, or strapped with adhesive strips to the splint. In lieu of this, a method which I often employ is to cause either cotton or wool sheet-wadding—cut of the required size and of double or triple thickness if needed—to adhere to the splint by a few strokes with the paste-brush. This saves quite a little time.

The term "coaptation-splint" is usually employed to designate an affair of thin wood, backed by thinner leather or cloth, and split through at frequent parallel intervals down to the backing; thereby permitting this short splint to be wrapped around the limb just opposite

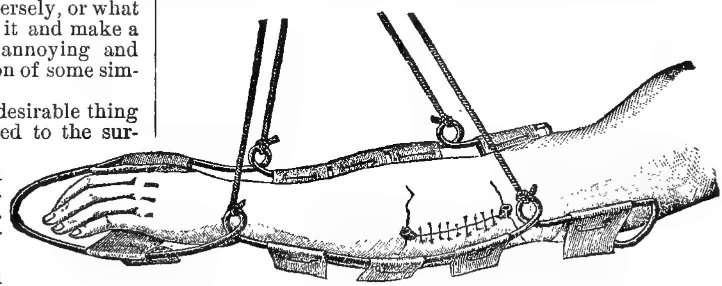

FIG. 3674.—Wire Splint for Horizontal Suspension of the Arm.

the line of fracture. It is often used to prevent lateral motion, in conjunction with some extension apparatus.

Carved and elaborately contrived wooden splints innumerable are in the market. Fig. 3670 indicates one, as a sample. This one, like almost all of them, can be perfectly supplanted by a plastic splint, with or without a telegraph-wire skeleton, and which can be made and fitted in place by the surgeon in half an hour.

Fracture-boxes properly belong in the list of wooden splints. They are generally elevated, to permit of easy return circulation, and have hinged sides. In the inflammatory stage of a compound fracture it may be wise to rest the limb in such an apparatus, dressed and bolstered with small cheese-cloth bags filled with moistened antiseptic sawdust, bran, or peat. At the present day, however, fracture-boxes are not much in vogue.

Although not strictly a part of the subject, it may be well to note that heat and annoyance from weight of bedclothing on the lower limb may be avoided by the use of a protecting cage. Such a contrivance can easily be made in a few minutes with three half-hoops from a barrel, and three laths, the whole being bound together firmly at the points of contact.

With a similar, but somewhat stouter, cage a supporting point can be given for a moderate degree of suspension, as indicated in Fig. 3671.

Still another simple and practical apparatus —although not a splint—is Volkmann's sliding leg-rest, made of three-sided wooden strips, shown well in Fig. 3672. By diminishing friction, it enables extension to be effectively accomplished with a minimum of weight, and is much less cumbersome and expensive than the railways, with wheels, etc., for the same purpose, over or under which the leg rests or is slung.

Fig. 3673 shows a simple and satisfactory means of adapting the double-inclined plane to the upper extremity. In the treatment of fractures of the humerus some degree of abduction is often desirable, and Middeldorpf's wooden triangle is one method of accomplishing this.

In splinting the shaft of the femur the posterior double-inclined planes have been generally supplanted by the wire anterior splint of Nathan Smith, which better accomplishes the same object. Three main methods are used here after reduction: *a*, Simple immobilization by any means; *b*, immobilization plus horizontal extension; *c*, immobilization plus elevation, both leg and thigh being in flexion to relax muscular traction on the fragments.

Where the fracture is a very oblique one, the frag-

ments readily sliding past one another after reduction, shortening will probably best be limited by horizontal

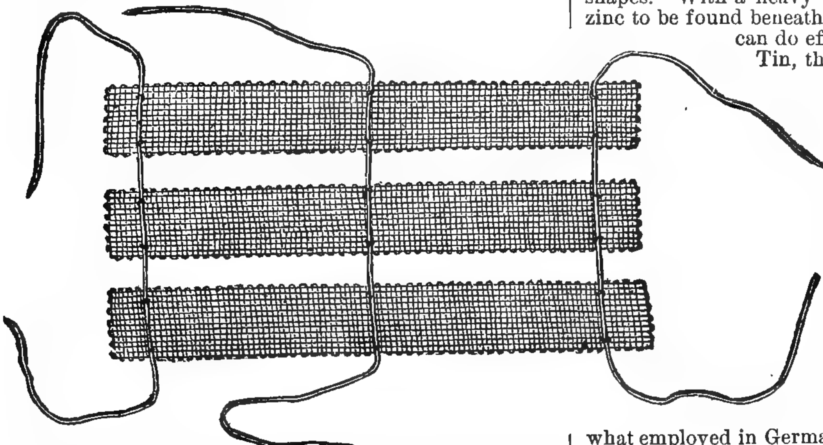

FIG. 3676.—Strips of Wire Gauze, bound together, ready for Application.

extension. In Smith's method extension cannot be effectively accomplished, the splint being fastened to the thigh above the point of fracture and to the body. However, some modification, as Hodgen's, in which the pelvis is not reached by the splint, may permit effective extension by this means.

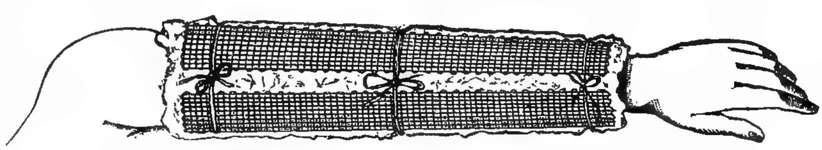

FIG. 3677.—Wire-gauze Splint, with Cotton Padding, applied to the Arm.

Smith's splint, easily made of bent telegraph wires by anyone, seems worthy of much attention, as representing a principle. It has been discussed under Fractures. Regarding the upper extremity, the same idea is illustrated in Fig. 3674.

Wire of telegraph size, or larger, is much used to-day, either embedded in plastic splints as a stiffener, or as a skeleton frame, simple in manufacture and easily made aseptic. Such a wire leg-splint, with foot-pieces and horizontal rest, is shown in Fig. 3675. Sheets of wire gauze, cut of the proper size, are sometimes employed, properly padded—Figs. 3676 and 3677.

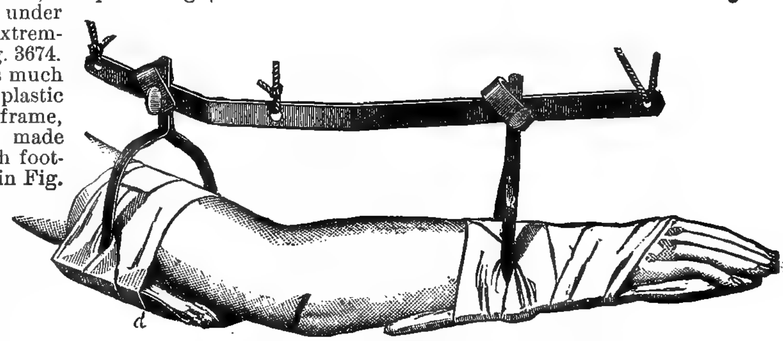

FIG. 3678.—Esmarch's Apparatus for Suspension of a Limb.

An excellent example is seen in Fig. 3678, of a simple iron suspension-splint, arranged to permit easy freeing for passive motion and change of angle. This is a device of Esmarch, from whose works several cuts in this article are taken, others being after Hueter, Volkmann, Neuber, etc.

Metal is in very few instances employed directly in contact with the tissues in splinting—for example, in Malgaigne's hooks for fracture of patella or their modifications, and in Hahn's nails, or screws, etc., for excisions.

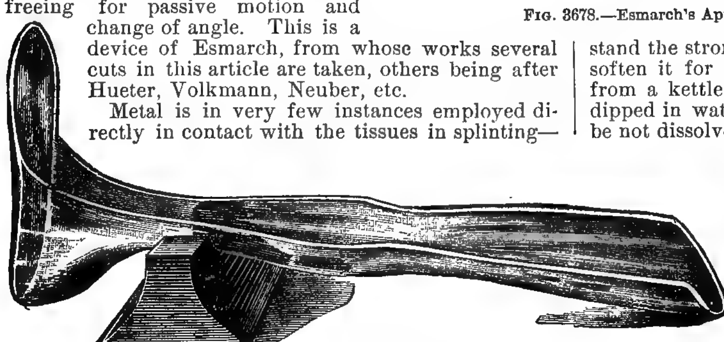

FIG. 3679.—Neuber's Glass Splint.

Sheet-zinc splints are in one sense plastic, since they can be bent and hammered with moderate ease into desired shapes. With a heavy pair of shears and the sheet of zinc to be found beneath almost every stove the surgeon can do effective work.

Tin, that is, tinned sheet-iron, if of ordinary thickness, is rather too flexible for use in extemporized splints. It can be bought stamped into fairly rigid shapes, as for shoulder-caps and Colles'-fracture dressings, etc.; but, as previously remarked, properly extemporized splints are very apt to be best. Narrow strips of tin, with a number of nail-holes driven in them to hold the plaster, are often employed between the layers of a gypsum splint to effect rigidity with slight weight.

The glass splint—such as that of Neuber, Fig. 3679—is somewhat employed in Germany, especially where continuous irrigation or wet dressings are intended. It can easily be rendered aseptic, but its cost and brittleness render it practically out of the field.

Turning now to the more or less plastic group, we find as its most prominent member pasteboard. Of various thicknesses, from mill-board or binder's-board downward in the scale, decidedly cheap, light, and easily moulded, it is an excellent splinting material, and one greatly used in place of wood in New York. It can be obtained thick enough to stand the strongest strains, if doubled. The best way to soften it for plastic purposes is to hold it in steam, as from a kettle, until it yields readily to pressure. If dipped in water, be careful that too much of the sizing be not dissolved out. For short splints the covers of an old book can always be utilized. Fig. 3680 indicates a simple method in which stout pasteboard can readily and without softening be made to form an angular splint for the elbow. Two lines running lengthwise, and the width of the limb apart, are to be barely scratched, to insure the pasteboard bending along them. The transverse line is also scratched, and then cut through from the edges as far as the longitudinal lines. The splint being firmly tied at any desired angle by cord passed through holes in it, is padded to fit. Fig. 3681 shows the same splint applied.

Fig. 3682 is a mill-board model for a shoulder-cap.

The lines A B, C E, and D E, are to be cut completely through. Fig. 3683 shows—the shading, however, being omitted—the inside of the same when in shape for application. The angles C B E, and D B E, in the former figure, are seen to cross one another in this, strengthening this part of the splint. Through the holes indicated the cord is passed which holds the splint in curvature. A moderate amount of steaming or soaking makes the shaping a more easy matter. The interior is, of course, padded with wadding. These examples are merely a few of the many ways in which pasteboard and similar material can be used.

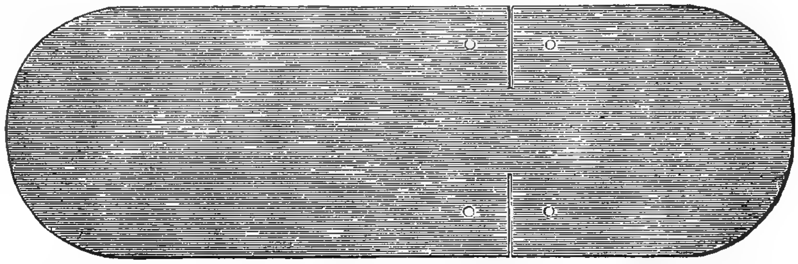

Fig. 3680.—Pattern of a Pasteboard Arm Splint.

Felt—well stiffened by shellac—is not commonly available for extemporaneous splinting, and is rather expensive. It is moulded by exposure to either moist or dry heat.

Either sole or bridle leather may perhaps be found at hand, and soaked in hot water it becomes quite pliable, and subsequently and rapidly stiffens. In country practice fresh bark, from most smooth-barked trees, especially if taken during the time that sap is rising, can be modelled sufficiently well for good work.

Of late, veneering has been considerably employed in one or two of our hospitals. It comes in very thin sheets of white-wood, extremely cheap. Hot water renders it almost as easily bent as pasteboard, the new shape being retained when dry again.

A very valuable splint is that introduced by Schede, of Hamburg—made of vulcanized rubber. This, in thin strips, can be bent to the desired shape by immersion in very hot water, or by oiling and heating, as with a spirit-lamp. When cold it is entirely rigid, and can be easily rendered aseptic.

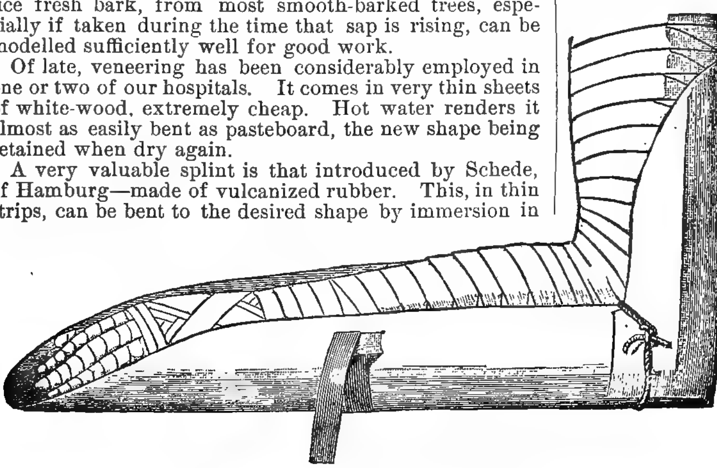

Fig. 3681.—Pasteboard Arm Splint in Position.

Celluloid splints may be substituted for the vulcanite, and moulded somewhat by the use of boiling water. It would hardly do to use oil and the lamp with them, celluloid being almost as inflammable as gunpowder.

The list of entirely plastic materials which I have given comprises several which are not commonly practicable, nor perhaps even desirable, as a first choice. Probably the oldest, as it is also the best, of the plastic splint materials is plaster-of-Paris (gypsum). This substance, after being pulverized finely and heated so that its water of crystallization—which is about one-fifth of the gypsum—is driven off, is in fit condition to use. If it is now wetted, it will reabsorb water and crystallize (set) into a mass almost as hard as stone. It is an interesting fact that, if in making the gypsum anhydrous the heating be carried too far, the "setting" will thereafter not occur, the affinity for water being destroyed. The objections to plaster are few—the only urgent one being its relative weight. This can be in part overcome by a method to be mentioned subsequently. The advantages of plaster are numerous—it sets quickly, and yet not too rapidly for a skilled worker; it is very cheap; is easy and not sticky to handle; is porous, and does not shrink in setting.

The best to work with is fine dentist's plaster, recently prepared and kept protected from the atmosphere. This will set in about ten minutes; but should the specimen be an old one, the splint may remain soft an hour or even longer. In an emergency very good work can be done with the common gypsum to be obtained of any plasterer, which should generally, before using, be freshly baked on a stove until moisture is no longer given off.

If it be desired to hurry the setting, the use of hot instead of cold water will do this. Also, the less water used, the quicker the hardening. Common table-salt dissolved in the water will also hasten matters, as would almost any crystalline substance. Either alum, silica, or cement-powder may be used, but salt, being the cheapest, is most commonly employed. I think that when salt has been freely employed, the splint, although setting quickly, is not quite as rigid as it would otherwise be. The use of dry heat will be referred to presently.

Setting may be retarded by the addition of starch, dextrine, glue, mucilage, gelatine, beer, milk, or borax; or by using plaster which has been exposed for some days to the air.

In regard to the material employed as a vehicle for the plaster, it is rather indifferent—any loose-textured fabric will do, and if properly made the splint will be sufficiently strong. For most purposes cheese-cloth or other gauze bandages, rubbed with dry plaster while being rolled, are best. These being stood in water, on end, until all the bubbles escape, are then, thoroughly wet, to be applied without reverses, which are here quite unnecessary. After from three to six thicknesses of such bandages, each thoroughly rubbed and smoothed with the hands before the next is applied, a final coating of dry plaster, dusted on and rubbed in as it moistens, leaves a surface

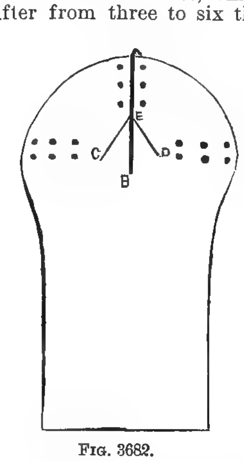

Fig. 3682.

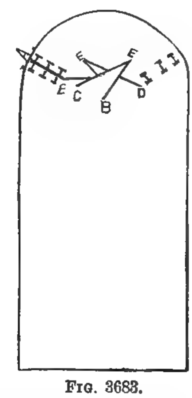

Fig. 3683.

Figs. 3682 and 3683.—Mill-board Model for a Shoulder-cap.

very smooth and even. If now the splint be hot-ironed with an ordinary flat-iron, or, as I have seen used, with a miniature stone garden-roller, the heat so applied drives off the superficial moisture, aids rapid setting, and leaves a rather glazed surface. This method of hastening the setting of the plaster is hardly worth the trouble it takes, except in the application of the plaster jacket to the body, in cases which do not bear kindly the partial suspension necessary.

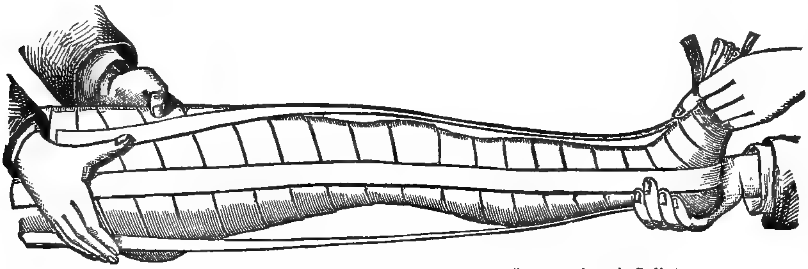

Fig. 3684.—Wooden Strips to be incorporated in a Plaster-of-Paris Splint.

To avoid the weight of a splint made as just described, we often employ stiffeners of various kinds placed between the bandages, and in lieu of some of them. For instance, thin wooden strips (Fig. 3684), or pieces of pasteboard, or strips of wire-gauze or of tin are used.

For field work, a readier means than that just given—unless gypsum rollers are at hand—is the Bavarian or book-back splint, or some modification of it. This is figured elsewhere (Fig. 1338, Vol. III.). It is sufficient, therefore, here to say that cloth, as, for example, a blanket of doubled thickness, has a straight seam sewn through both layers, which seam is so placed as to run along the back of the limb; plaster cream is spread thickly between these layers, and they are wrapped about the limb. When the splint has set it is opened in front, and the seam at the back acts as a hinge. The two halves are held in contact with the limb by straps or a roller.

A favorite method with the late Professor Little, of this city, was to cut several thicknesses of cotton-cloth or muslin the length of the splint desired, and not quite wide enough to meet in front at any point, so that an uncovered longitudinal strip of skin is left. These layers were then immersed and thoroughly soaked in plaster of the consistency of cream, and applied directly to the skin, which was either simply oiled, or, if hairy, shaven and oiled. A roller-bandage held the splint in place, and, after setting, this was cut away in front. Such a splint is easily sprung off, and on again. Gypsum splints possess considerably more of elasticity than would naturally be supposed.

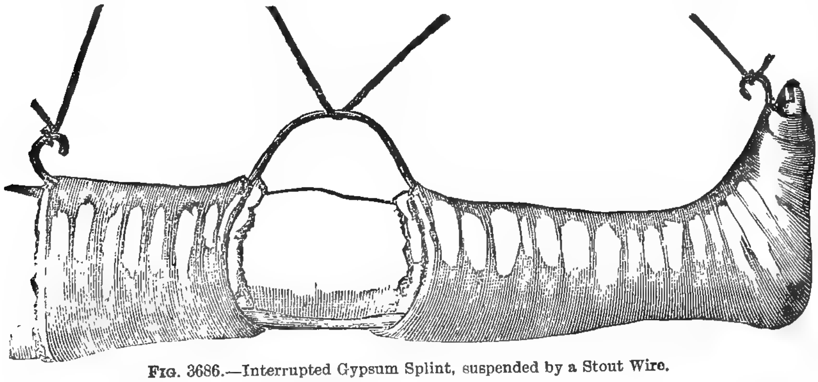

Fig. 3686.—Interrupted Gypsum Splint, suspended by a Stout Wire.

It is not usual to allow the gypsum to come into direct contact with the skin, as in the instance just mentioned. In the Bavarian splint the inner layer of blanket is the protection. When the ordinary method, with the plaster bandage, is the one adopted, it is best to cover the limb first with a flannel roller, or else with a layer or two of woollen, or several layers of cotton wadding—the latter being thinner than the woollen. *Wadding*, rather than *batting*, should be employed, the wadding being of uniform thickness. Whether flannel roller or wadding be our choice, it should be turned up over the ends of the plaster splint, in order to protect the flesh against a sharp edge.

If we wish to have our result appear extremely neat and workmanlike—certainly, next to the patient's safety and comfort, an object to be desired—we may wrap about the limb two strips of plush or velvet, each three or four inches wide—with the nap turned toward the skin—marking thus the upper and lower limits of our splint. The limb between these strips is to be covered as usual by flannel or wadding. The plaster roller then applied covers one-half the width of each strip, and, when the splint begins to harden, the strips are turned up over its ends, bringing the right side of the plush or velvet outermost.

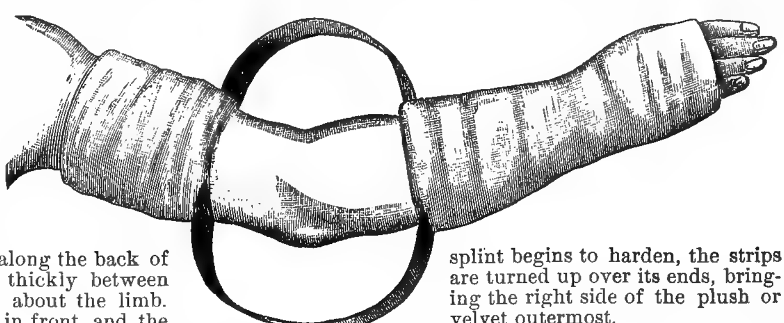

Fig. 3685.—Interrupted Gypsum Splint.

Gypsum splints made with an interruption are often used, as in compound injuries, or in excision of joints. Fig. 3685 shows such a splint, interrupted by ordinary hoop-irons embedded in the plaster, and sufficiently arched to allow the application of thick dressings between them. In Fig. 3686 is shown a similar splint, but suspended from a stout wire properly bent, and running along the front of the limb between the layers of plaster bandage. Here, in order to remove any possible danger of flexion, a posterior wooden splint is first applied, and over it the plaster.

When the presence of a compound fracture, or some other reason, compels the formation of a fenestra in the splint, this is best made as follows: Covering the wound, a saucer of the proper size for the fenestra is placed, bottom upward. Over this the usual plaster is applied, and when it has set the prominence made by the saucer easily enables one to cut out a circle of just the right size, at the right spot. This is better than using a wad here, being as sharply defined, and avoiding the pressure on the wound which the latter necessitates.

Fig. 3687 shows a fenestrated splint. It is a mistake, in a case requiring immobilization of the knee, not to carry the gypsum up nearly to the body. If the splint stops low in the thigh, as figured here, muscular action is more apt to break it.

If there be a discharge from the wound, or if moist dressings are to be applied, it is necessary to protect the edges of the fenestra, and prevent fluids trickling between them and the skin. By far the neatest means of accomplishing this is to cause a sheet of thin rubber—gutta-percha tissue—to adhere to the skin all around the wound on the one hand, and to the external surface of the splint on the other, by painting the skin and the splint with strong liquor gutta-perchæ (gutta-percha dissolved in chloroform).

In young children it is best to paint with an alcoholic solution of shellac a plaster splint which, from its position, would otherwise be liable to become softened and broken through repeated wetting with urine. Shellac, moreover, prevents the gypsum from rubbing off, and thus marking dark clothing.

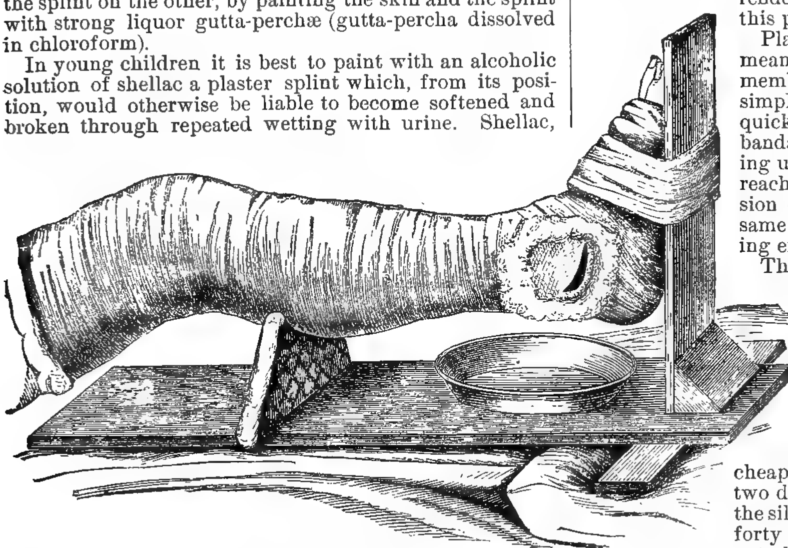

FIG. 3687.—Fenestrated Gypsum Splint.

The question how best to remove a plaster splint encircling either a member or the trunk, is a practically interesting one. The ordinary method is to endeavor to cut through it by the aid of a knife and much muscular effort. As a plaster dressing becomes about as hard as stone, such attempts are not soothing to the temper. The violent efforts made are also more or less dangerous to the patient, if the knife be not carefully guarded.

If the surgeon employs gypsum with some degree of frequency, it will repay him to procure the instruments shown in Figs. 3688 and 3689, or some modifications of them. The saw, on the plan of Hey's saw, will be valuable. The plaster shears selected should, like these, have a flat under-blade, great leverage, and an ample grasp for the hand, and should not, like Esmarch's, have scissor handles through which only a finger and thumb can be passed.

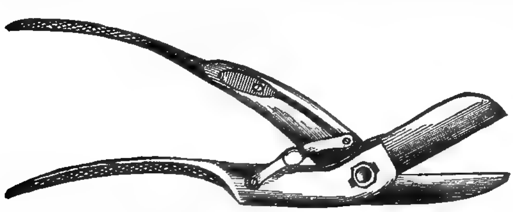

FIG. 3688.—Szymanowski's Plaster Shears.

For those who but semi-occasionally use plaster, there are other expedients which will lessen the fatigue. For instance, with a glass rod dipped in some strong acid capable of attacking the plaster—as nitric—draw a line where it is desired to make the section. With a cheap knife—for the acid will ruin it—cut along this line. Repeat the line of acid, and then the cutting, as often as needed. Each application of the acid will enable the cut to go a little deeper, without much effort.

Another method is to lay upon the splint cloths taken from boiling water, and repeat again and again. After a quarter of an hour of steady application the softened splint may be cut with moderate ease.

Still another expedient: Soak a narrow strip of cloth, or a piece of tape, in sweet-oil, and place it along the limb, upon the wadding or other subdressing, at the line to be subsequently cut. Then apply, over strip and all, the gypsum dressing. It will be found that the oil renders the plaster somewhat softer at this point than elsewhere.

Plaster splints, however, do not by any means necessarily always encircle the member. Their shapes are legion. A simple straight splint, for instance, is quickly made by running the wet plaster bandage up and down the limb, repeating until a sufficiently great strength is reached. An anterior splint for suspension can be fashioned with ease in the same way, wire loops for the tackle being embedded at proper intervals, etc.

The silicates ("water-glass") as a plastic agent have the advantage of extreme lightness of the splint, when hard; but hardening requires a long time—nearly three days with silicate of soda, which is cheaper than that of potash; two days with a mixture of the silicates; about thirty to forty hours with silicate of potash; and less than a day if some substance, such as magnesia, chalk, slaked lime, or cement be freely mixed with the solution, making it of a consistency like that of honey. In this way it will dry more quickly than a starch bandage, though, of course, not nearly so rapidly as gypsum.

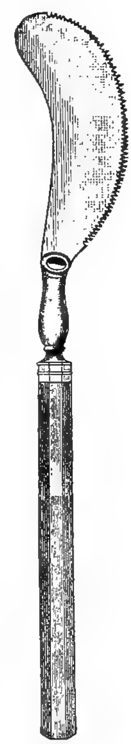

FIG. 3689.—Plaster Saw.

A saturated solution of the silicate desired is made, and bandages or other material are soaked in this, and applied just as with plaster. It is very sticky, and hence more disagreeable to manipulate than the latter. The solution should be freshly prepared, as, if old, it is capable of irritating the skin quite severely. When the splint is in place, a final brushing with alcohol will leave a surface of almost glassy smoothness.

It is, of course, essential that the limb be held rigid while setting is going on, and therefore a temporary wooden splint over the water-glass is needed. If a jacket for the body be desired, some surgeons have advocated covering the silicate splint with one of plaster-of-Paris, the latter to be cut off and removed later, when the water-glass splint beneath has hardened. This seems to the writer unnecessary trouble, as a simple plaster jacket can, by the aid of stiffening strips, be made to combine lightness with strength. The water-glass jacket may be cut like that of gypsum, and held together with straps or lacings.

Most of the remaining plastic materials are hardly worthy of detailed notice as a first choice, because of relative expense, of too prolonged or too brief a period of setting, or of various other objections.

Starch is sometimes employed, made by stirring with cold and then adding boiling water. The thick mucilage resulting is either brushed on layer after layer of applied bandage, or the fabric used is first soaked with it and then applied. This makes a light, cheap dressing, but hardens slowly—in thirty to forty hours—and contracts somewhat. Flour paste, or white of egg and flour, may be used as a substitute.

Dextrine—"British Gum"—is made by adding dilute

sulphuric acid to starch at boiling-point. It is dissolved in as little alcohol as possible, plus a little water. Camphor added seems to aid hardening. Apply as with starch.

Thick glue, to which alcohol is added to promote more rapid drying; glue or mucilage and chalk—as, equal parts of gum arabic and precipitated chalk; or glue and zinc oxide, will effectually stiffen the material with which they are impregnated. The second mixture hardens more rapidly than starch, requiring from four to five hours. The third sets still more quickly, though quite slowly as compared with gypsum. Too great a proportion of oxide of zinc should be avoided, as it renders the splint brittle.

Gutta-percha makes an excellent but rather expensive splint. That it is not sufficiently porous is an objection urged against it, in common with several others of this group. A sub-dressing is always used, and this objection seems to me, therefore, unimportant. The gutta-percha should be softened by immersion in *warm*, not *hot*, water. If the latter is used, the outside will become very soft and adhere to everything it touches, before the rest is affected by the heat. When warmed through and softened so as to be workable, it may be made flat and of any desired thickness, by means of a wet rolling-pin on a wet board. Then soften again and instantly apply. It sets almost at once, requiring rapid work.

Tripolith is a substance which also sets very rapidly—too rapidly, in fact. It is a gray powder, of lime, silicon, and iron oxide—not so heavy as gypsum, and is manipulated by the same methods as the latter.

Either paraffin or stearin may be used, melted and painted freely on the bandaged limb with a brush. Such splints are not quite as rigid in midsummer as in cold weather. In removing them, a hot blade aids the cutting.

In an emergency, clay moistened and rubbed thickly into and upon the meshes of the roller, or other sub-dressing, will do. As with many of the dressings already described, the application of dry heat about the finished splints—as by hot bricks, or bottles filled with boiling water—will aid evaporation and shorten the tedious hardening process.

Shellac cloth—as several layers of cotton cloth soaked in a saturated solution of shellac in alcohol and pressed together into a solid whole—may be obtained ready prepared; it makes a very desirable splint, and one which is rendered perfectly plastic by immersion in hot water, and afterward sets moderately quickly. As compared with a gypsum splint, it is, of course, more expensive.

A similar dressing may easily be extemporized, if desired, by soaking sheets of blotting- or wrapping-paper, or thin cloth in the shellac solution just mentioned, or in collodion. In a case of Pott's disease recently published, the operator, Dr. Taylor—not having gypsum or any splint material other than this at hand—first made a mould of the back with shellac blotting-paper, and when this mould had hardened, added to it alternate layers of fresh shellac blotters and glued coarse linen, until sufficient resisting power had been produced.

As a splint, adhesive plaster is only in one sense properly a member of this group. It does not "set." It is not much harder when cold than when warm, being easily flexible at all times. But in several instances it has been advocated as a splint, notably in Pilcher's method of treating Colles' fracture, which consists in supporting the fragments after reduction by wrapping a number of times about the wrist a narrow strip of adhesive plaster, until the splint is about two inches wide and moderately stiff and firm. Rubber plaster is rather too soft for this purpose.

This is only one among scores of different devices for the cure of this particular bone-lesion. It seems to the writer that it is rather a trivial matter which splint be chosen in Colles' fracture, and not worthy the numerous volumes which have been devoted to it. If the fragments have been disengaged and restored to good position, any splint which will keep them quiet is the right one. If the fragments have not been properly reduced, no splint will do this, and deformity will be inevitable.

In concluding this article, it is hardly necessary to say that much of the subject-matter is as old as Surgery, and for the rest the writer is largely indebted to very many authors well known in their specialty.

Robert H. M. Dawbarn.

SPONGE (*Éponge fine*, Codex Med.). The household articles known by this name are the horny or silky skeletons of several species of invertebrate animals belonging to the Order *Ceratosa*, in the great Group *Parazoa* or *Spongiæ*. The commercial sponges are colonial in their composition, although the outlines of individuality are very obscure. They are soft, porous, gelatinous bodies, perforated by numerous openings communicating with irregular, ramifying cavities within them, as well as with digestive and respiratory chambers, and more or less regular tubes or canals. These minute chambers are lined with flagellated cells, which are probably the organs of nutrition as well as those by whose movements a constant stream of water is kept flowing into the sponge through the fine pores and out through the larger openings. Sponges are all aquatic, and those of commerce all of marine origin, growing upon rocks or other firm foundation, at a depth of from six to a hundred or more feet below the surface of the water. They are of slow growth, requiring from three to six years to attain a useful size. The mode of collection varies with the depth at which they are found as well as with the habit and outfit of the collector; sometimes they are torn off the rocks by tongs or hooks, sometimes dredged for, but more generally they are gathered by divers from boats; these again may go down unprotected for three or four minutes at a time, or, equipped with modern diving-suits, make longer and deeper searches. Finally, the cultivation of sponges by fastening bits upon boards or sticks, and then sinking them to the bottom, has been proved practicable. When the sponges have been brought to land they are rubbed with sand or bruised to break up the soft parts, or exposed to the air until decomposition sets in, and then repeatedly washed and squeezed until they are clean. They are then dried and sent to market, where they are carefully trimmed and assorted, according to kind, fineness, size, and shape, into numerous grades.

There are several distinct kinds, dependent upon the species producing them:

1. The *Levant* or *Turkey Sponge*, from *Euspongia* (*Spongia*) *officinalis* Linn., the finest and most expensive of all, from the waters surrounding the Grecian Islands, Asia Minor, Syria, etc. It has a soft, fine, very elastic texture, a light color, and great toughness of fibre. In shape it is rounded, tuberculated, lobed, hemispherical, cup-shaped, or irregular: it is very free from its gelatinous flesh when prepared for the market.

2. The *Zimocca Sponge*, from *Euspongia Zimocca* O. Schmidt; also a fine, strong, valuable sponge, but harsher to the feeling than the preceding, and not nearly so expensive.

3. The *Mediterranean Bath Sponge*, from *Hippospongia equina* O. Schmidt; in large, soft, rounded masses, with a loose texture and very large reticulating canals.

Besides these, this country is supplied in great abundance with very cheap sponges from the West Indies; they are much inferior in texture and durability to the Mediterranean products: they are,

4. The *Reef Sponge*, *Euspongia officinalis*, var. *tubulifera*, is the common cheap, fine "slate sponge," it is coarser, less elastic, and very much more tender than the Turkey sponge, and is of more or less conical shape, with a broad, cut base.

5. The *Sheepswool*, *Velvet*, and *Grass Sponges*, from various species of *Hippospongia*.

Composition.—Sponges contain a considerable quantity of fine sand, and sometimes pebbles, entangled in their meshes, which can generally be removed by mechanical means; there is also a varying amount of calcareous concretions or fragments, which stick more tenaciously and often have to be dissolved by dilute acid. These being removed, the remainder is nearly all a peculiar elastic, durable, nitrogeneous substance called *Spongin*, closely

related in composition and texture to silk. Besides this, there are a little iodine, bromine, salt, etc.

USES.—These are mostly mechanical or household, and familiar to everyone. Carbonized sponge, *Spongia usta*, now obsolete, used to be given for the same conditions for which iodide of potassium is now used, and owed its value to the presence of that element.

In surgery sponges have long been used for packing and dilating cavities, and as absorbers of blood in operations. The general acceptance of antiseptic methods in surgery has caused them to be looked upon less favorably than formerly, and requires a special preparation before they are to be used at all. For surgical operations the fine, soft, Turkey sponges, though dear, are the best. With care in washing and sterilizing, in private practice they may be used repeatedly, and so their first cost made less of an objection, or the fine West India sponges may be used once and thrown away. The bath and sheepswool varieties are too porous and soft to be of any use as blood-absorbers. A sponge of a size convenient for the hand and operation, and of a rounded shape, without large canals or deep constrictions, should be selected. They may be bought already bleached or, better, unbleached, and bleached by the surgeon, who should always superintend the sterilizing and preservation of them. They may be bleached by a chlorine solution, being carefully watched, and removed before they have acquired a bright, golden-yellow hue; it is, however, a poor method, and apt to rot them. Dilute sulphurous acid or a bromine solution is better, but perhaps the best method of all, for surgical use, is that by means of permanganate of potash and oxalic acid, as follows: After beating and shaking, or dissolving out all mineral impurities, soak the sponges in a strong (say, one per cent.) solution of permanganate of potassium, then rinse them and wash in a solution of oxalic acid, strong enough to taste sharply sour, stirring and pressing them until the color of the permanganate is entirely discharged; then wash very thoroughly with clean water. If they are not white enough, repeat the whole process again, but do not leave the sponges longer than necessary in the acid. They are then bleached, but not sterilized; for the latter purpose soak them for an hour or more in a five per cent. solution of carbolic acid, to kill active organisms; wash in clean water until the carbolic acid is removed, then set in a pail of water in a warm place for twenty-four hours in order to germinate the spores, and finally put again in five per cent. solution of carbolic acid. They may be kept in this solution, renewing it occasionally, until needed, or they may be pretty safely put in a sterilized bag of several thicknesses of close cotton cloth and kept dry until wanted. Corrosive sublimate injures sponges very quickly, alcohol shrinks them and temporarily destroys their elasticity, hot water damages them permanently, and alkalies or strong soap-solutions dissolve them. After having been used, the cleansing and sterilizing process is to be repeated in full.

Sponge tents, now but little used, are made by soaking fine, tough sponge in melted cocoa-butter, or in mucilage or alcohol, and winding very hard to cylindrical shape with strong twine; when dry or cold the cord is removed and the surface is filed or pared to shape.

Ether sponges are fine Turkey sponges of large size, requisite fineness, and of a regular cup-shape. No inhaler has yet been made so safe or comfortable to the patient as these, but they are wasteful of ether. *W. P. Bolles.*

SPONGE-GRAFTING. The recent introduction of sponge-grafting as a means of promoting the repair of chronic ulcers and other solutions of continuity rebellious to ordinary treatment, has proved of such service in the hands of those who have resorted to it, that we cannot too urgently advocate its claim to the attention of the surgeon. We are indebted to D. J. Hamilton, the distinguished Professor of Pathological Anatomy, Aberdeen University, for the introduction of this material for the cure of ulcers.

That we do not here exaggerate the value to be attached to sponge-grafting, the relation of the following case, occurring in the writer's practice some time since, amply demonstrates. This case presented itself just at the time when the writer was in receipt of a letter, accompanied by a package of sponge, from Professor Hamilton, and it was determined to make a practical test of the method at once. Pieces of these sponges were adjusted to nearly every portion of the ulcerated area, covered with oil-silk, and daily cleansed with carbolized water. When it became necessary to remove any piece of sponge which had not remained aseptic, the bare spot was at once covered with a fresh piece. This treatment, persevered in for one month, brought about a gradual development of granulations, and finally resulted in a perfect cicatrization of the ulcer. It is worthy of note that this case had been under treatment for a very long time, and the presence of the offensive discharge had evidently influenced the general health of the patient; but notwithstanding this, and the fact that the area of ulceration was so extensive, the wound healed promptly under this treatment. It is equally of importance to state that there has been but little contraction of the cicatricial tissue, though several years have now elapsed since recovery.

In almost every hospital ward the surgeon is confronted with a class of ulcers that persistently resist all attempts to promote their healing. Repair can take place only through a healthy granulating process, and when cicatrization is postponed the cause must be referred to some abnormal condition of the granulations. The several forms of diseased granulations, whether fungous, hæmorrhagic, croupous, or diphtheritic, may be rendered healthy by well-directed treatment. But it often happens that, in the absence of any specially diseased state of the granulations, unless it be the want of nutritive power to sustain themselves, their functional activity becomes too soon exhausted, and, in consequence, the process of cicatrization is delayed. In this state of relaxation and collapse, all granular appearance disappears, cell-proliferation ceases, pus-cells no longer emigrate, the vascular loops droop, fall over, become thrombosed, degenerate, and disintegrate; and this morbid process is repeated as often as the pressure from below forces other vascular loops to the surface. To offer these weak and disorganized granulations a surface support through contact with some more vitally endowed tissue, is the indication which naturally suggests itself, and which might well have been fulfilled at the time when John Hunter showed the possibility of grafting living tissue upon a denuded surface, when he transplanted the cock's spur upon the stump of its comb. It was, however, reserved for Reverdin, only a few years since, first to put into practice his method of skin-grafting. However productive of the best results this method has often proved to be, yet, it must be confessed that skin-grafting is neither agreeable, expeditious, nor always available. The application of sponge-grafting, on the contrary, as a ready means of cure—for the material is always at hand and can be easily prepared—presents an interesting subject of contemplation to the histologist as well as to the pathologist in the mode by which it accomplishes this end.

It is well known that a living tissue may take root, become nourished, grow, and cover an abraded surface with which it is retained in contact; but the interest attached to the sponge in this connection is of a very different nature, for we are here making use of a material which is neither organized nor living. The question arises, in what way does such a material promote rather than, as a foreign body, impede, cicatrization? Looking critically into this subject, in order to offer a demonstrative explanation of the agency of the sponge in securing, maintaining, and assisting in such a process, we must first consider the mode in which organization takes place in a blood-clot.

It was formerly believed by most physiologists that the coagulation of blood was a proof of its vitality. The clotting of fibrin and its subsequent fibrillation was supposed to be a spontaneous assumption of structure, since there is a felt-like, matted arrangement of decussating

fibres, wholly unlike the granular and homogeneous particles of coagulated albumen, through and among which blood-vessels appeared to be developed *de novo*. But a closer examination has shown the fallacy of this view. The clotting of fibrin is now known to be an evidence of the death, not of the life, of the blood. Within the interspaces of this fibrillated stratum loops of blood-vessels are projected from the deeper-seated structures, while leucocytes and blood-corpuscles are entangled within its meshes; whatever vitality these corpuscles at first possess is very soon lost; degenerated and destroyed, they finally disappear with such few blood-disks as may at first be found in the clot. The underlying, distended, and tortuous blood-vessels are displaced and pushed out farther into the clot, carrying with them connective-tissue corpuscles which, proliferating, insinuate themselves as broods of cells into the interfibrillar spaces. The fibrinous network now contracts, expresses all of the serum therein contained, begins to fall to pieces, and finally itself disappears; and all of this is coincidently connected with the destruction, through fatty or granular change, of both orders of blood-cells. There seems, therefore, to be no evidence to support the views of Cohnheim and others, that a blood-leucocyte is converted into fibrous tissue. The subsequent cicatricial or fibrous tissue owes its origin, not to these corpuscles which disappear, nor again to the original fibrin-clot, which also is sooner or later removed; for it is known that the fibrous tissue ultimately formed into cicatricial structure, is not that first seen in the blood-clot—the original fibrinous material which the extravasated blood furnished—but newly-formed fibrous tissue evolved through the morphological changes of the connective-tissue corpuscles. So far, then, as the original clot was concerned, it may be said to have been perfectly *passive*, having, through its elastic and porous arrangement of fibres, served the purpose of a trellis-work, supporting the growing cicatricial tissue. The embryonal cells may actually be seen to elongate into spindle-cells that are slowly transformed into the fibrous tissue which forms the cicatrix.

Another point of interest and worthy of careful study, is the mode by which the vascularization of the new tissue is established. According to many writers, this is accomplished by the actual development of newly-formed blood-channels, but, notwithstanding the scientific authorities who support this view, Professor Hamilton has never been able to verify the production of new vessels; in no instance did he discover anything but loops of ready-formed vessels, the convex side of these being invariably directed toward the distal or peripheral parts, the concave toward the proximal; and he detected none of these vessels ending in free extremities. There was always a complete afferent and efferent vessel. "When such a loop reached the sponge framework," he says, "it was pushed into it, often some distance in advance of the cicatricial elements which usually surrounded these vessels. It still, however, maintained the character of a complete capillary loop, and I was unable to detect anything like a free, newly-formed, and pointed offshoot on examining other portions of these vessels for any evidence of sprouts from their sides; I must say I could not detect anything of the kind. . . . Another curious point—if these vessels were newly formed—was that the stems leading up to the capillary loops at the edge of the cicatricial layer possessed, in many cases, a completely formed adventitious coat . . . the appearance of fully developed capillaries, without any evidence of offshoots branching from them."

From this investigation of nature's method of organization of the blood-clot, we learn that the fibrin fulfils the passive purpose of a framework for the support of vessels, not of new formation, but of such as are forced into it from subjacent parts, surrounded by connective-tissue corpuscles, whose polynucleation and subsequent germination eventuate in a progeny of new cells, migrating into every interspace, aggregated into clusters which press destructively upon each and every fibrillar shred of the network, and finally constitute themselves the progenitors of the incipient cicatricial tissue.

Now, let us compare this process in the blood-clot with that taking place in the sponge, when used in the manner which we shall describe. Sponge closely resembles in its porous nature the trellis-work of a fibrillated blood coagulum, when through the proper method of preparation it has been converted into fine layers or sheets of extraordinary delicacy. If such a piece of sponge, properly prepared and rendered aseptic, be adjusted to an ulcerated surface, the feeble granulation loops of which need support, we can readily imagine that the subjacent capillaries will push themselves into its interstices, just as we see them do in a blood-clot. This organic connection, which the sponge contracts with adjacent and easily denuded surfaces, has indeed often been seen, and sometimes seriously realized, when, for example, a sponge-tent has been incautiously left too long imprisoned within the cervix uteri. Who has not met with difficulty in its removal, which has only been accomplished at the expense of a laceration of vessels that have penetrated the very meshes of the sponge, and which often is accompanied with considerable hæmorrhage?

These capillaries are under no restraining influence upon denuded surfaces, and are naturally forced out into loop-like processes under the constant blood-pressure derived from each propulsive action of the heart, to such an extent indeed, in all granulating wounds, that they often must be compressed or "kept under" by remedial agents daily applied to such exuberant granulations. It sometimes happens that these blood-vessels grow to such lengths that they fall over, their circulation becomes obstructed, and thus they fail to fulfil their purpose in wound repair. If, in such a case, the wicker-work of a sponge be placed so as to support the loops, they may then climb to the surface and establish a degree of vascularization which carries with it connective-tissue corpuscles from neighboring parts, out of which in time a true cicatricial structure may be formed. It is thus that sponge-grafting has been discovered to supplement, as it were, a natural process, and, on microscopical examination, is seen to bear the relation to neighboring parts which we have endeavored to demonstrate. It is needless to state that, as cicatrization advances, the new elements of reconstruction are found to press upon the meshes of the sponge, which, like the fibres of a clot, slowly disintegrate and are removed. During the entire progress of the changes that are seen in parts thus undergoing advancing cicatrization, the sponge texture becomes so infiltrated with tissue-corpuscles and filled to repletion with reticulated, convoluted, and looped vessels—in other words, so thoroughly vascularized—that it appears to the unaided eye to be actually organized; and it even bleeds at the touch, or when it is pricked by the finest pointed needle. Holding, as it were, upon a scaffold the elements of repair, while they are actually being converted into veritable tissue, the sponge seems to fulfil another important purpose, for it certainly thus prevents, or at least diminishes, the subsequent shrivelling of the cicatrix. This was well seen in the case above cited.

It only remains to state that this sponge must be rendered aseptic, and should, of course, be first deprived of all extraneous particles. It should be immersed in some weak acid to destroy every particle of inorganic material, after which it must be washed in liquor potassæ, perfectly cleansed again in distilled water; it is to remain for some days in a strong solution of carbolic acid, then dried, when it can be cut with a section-cutter into delicate layers, which may be kept ready for use, wrapped in oil-silk.

Middleton Michel.

SPRING LAKE MAGNETIC SPRING. *Location and Post-office*, Spring Lake, Ottawa County, Mich.

Access.—From Chicago by the West Michigan Railroad to Ferrysburg, less than a mile from Spring Lake; or by boat to Grand Haven, thence by Detroit, Grand Haven & Milwaukee Railway to Spring Lake; from Detroit by the Detroit, Grand Haven & Milwaukee Railroad.

ANALYSIS.—(Professor C. G. Wheeler). One gallon contains (50° F.):

	Grains.
Chloride of potassium	4.2880
Chloride of sodium	405.5330
Chloride of calcium	113.4200
Chloride of magnesium	36.2000
Chloride of sodium	0.9537
Bicarbonate of calcium	0.1808
Bicarbonate of iron	1.0060
Bicarbonate of magnesium	0.0640
Bicarbonate of manganese	0.0647
Bromide of magnesium	2.1700
Sulphate of sodium	46.7000
Silica	0.5030
Alumina	traces
Ammonia	0.0158
Organic matter	18.2702
Lithia	traces
Total	629.5692

THERAPEUTIC PROPERTIES.—This is a valuable saline water, containing an appreciable quantity of the bromide of magnesium. The claim to magnetism, which this and other springs in Michigan boast of, is not borne out by scientific investigation. This property is found to be due to, and to reside in, the iron tubing.

The waters are employed as a cathartic in diseases of the liver and digestive organs.

This spring is located in the town of Spring Lake (1,500 inhabitants), on a beautiful sheet of water of the same name. It is three miles east of Grand Haven, on Lake Michigan. The lake empties into Grand River, which forms the harbor of Grand Haven, and affords delightful boating and excellent fishing. There are several good hotels, provided with all the modern improvements necessary for comfort. There are also good facilities for bathing. *G. B. F.*

SPUNK (*Fungus Chirurgorum*, Ph. G.; *Agaric de Chêne*, Codex Med.; *Amadou*, etc.). A preparation made from *Polyporus fomentarius*, or *P. igniarius* Fries; Order, *Basidiomycetes* (*Fungi*).

Both the above fungi are parasitic upon the trunks of forest-trees, especially of oaks and beeches. They are attached by broad bases and expand horizontally in large, rounded, hoof-shaped masses of corky texture, and reddish- or grayish-brown color; the upper surface is convex and marked by a series of distinct concentric rings, each of which indicates a year's growth. The underside (hymenium) is flat. *P. igniarius* is a little flatter, rather smaller, and in an early stage more velvety upon the surface than the other; otherwise they are very similar. Both the above species are collected, as well as a few others, for making surgeons' styptic fungus or amadou; but *P. fomentarius* is said to yield the best quality.

For surgical use the middle portion only is taken, the top and bottom layers being cut away, and, after being softened in water, it is beaten with a wooden mallet into a tough, flexible, buckskin-like sheet, and dried. In this condition it will absorb more than twice its weight of water. It was formerly used to stop bleeding, by being packed or bound over the bleeding surface.

Spunk, properly so called, or tinder, consists of this "amadou," prepared as above and soaked in a solution of nitre or chlorate of potassium. It is very inflammable, burning without flame, but scintillating now and then, and holding fire for a long time. This, which is sometimes kept in the shops, can be prepared for surgical use by dissolving out the saltpetre in water, and drying. The blood-stanching action of amadou is entirely mechanical, and it is almost completely superseded by the excellent preparations of absorbent or styptic cotton, or by lint, "spongio-pilin," etc., with which the market is supplied.

ALLIED PLANTS, ETC.—See AGARIC, PURGING.

ALLIED SUBSTANCES.—Cotton, lint, charpie, and sponge are used now for the purposes for which amadou was formerly valued. See also MATICO. *W. P. Bolles.*

SQUILL (*Scilla*, U. S. Ph., Br. Ph.; *Bulbus Scillæ*, Ph. G.; *Scille*, Codex Med.). The bulb of *Urginea maritima* Baker (*Scilla maritima*, Linn.); Order, *Liliaceæ;* a perennial herb with an onion-like bulb, liliaceous leaves, and a long spike of regular, small, hexamerous flowers.

FIG. 3690.—Scilla Maritima; bulb and leaves. (Baillon.)

The bulb is large, four or five inches long, globular, covered with two or three dry reddish or gray papery scales, and made up within of numerous thick fleshy ones. The greenish-white flowers appear in the fall upon a scape one or two feet long, and form a spike nearly as long as the scape; perianth, six-parted; stamens, six; ovary, three-celled; seeds, fifteen or twenty, winged; leaves, vernal, narrowly lanceolate, one or two feet long.

Squill grows mostly, as its name indicates, not far from the sea-shore in dry, sandy places. It is native to nearly the whole Mediterranean coast, and is especially common in Spain. There are two varieties, the white and red, distinguished by the color of the outer tunics of the bulbs.

For medicinal use the bulbs are collected in the latter part of summer, the outer scales peeled, and the rest sliced transversely in slices from an eighth to a quarter of an inch thick, and dried in the sun.

It is then in quadrangular strips, two sides of which are covered with cuticle, the remaining two being sections; the strips are curved and shrivelled, of a whitish color, brittle if very dry, but hygroscopic and generally somewhat flexible, nearly odorless, and having a mucilaginous taste, becoming bitter and acrid. It consists of a simple parenchymatous tissue loaded with mucilage containing numerous oxalate of lime crystals, and traversed by occasional vascular bundles.

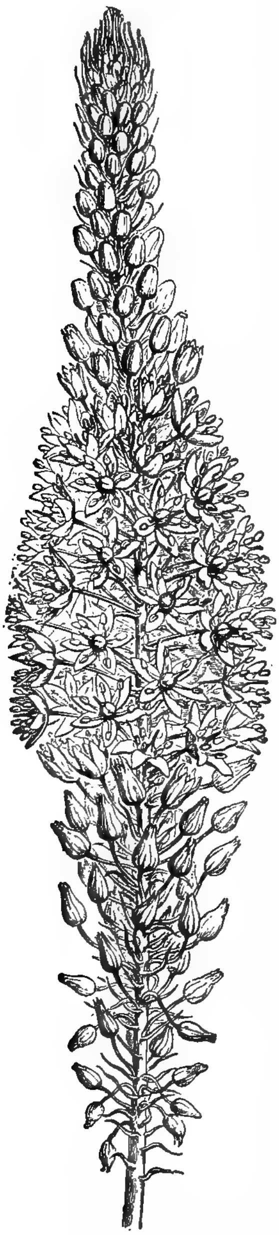

FIG. 3691.—Scilla Maritima: Inflorescence. (Baillon.)

Few medicines outrank Squill in antiquity; it is mentioned by nearly all writers upon medicine, from the earliest down.

COMPOSITION. — Besides the mucilage and some sugar and the oxalic salts, Squill contains a dextrin-like substance called *Sinistrin*, of no active properties. The principal ingredients are, a bitter, active principle, *Scillitoxin*, amorphous, light-brown, soluble in alcohol, not in ether or water, a cardiac poison resembling digitalis; *Scillipikrin*, a yellowish white, amorphous, hygroscopic powder, similar to the above but less active; and finally *Scillin*, of no medicinal qualities.

ACTION AND USE.—Squill has in a measure the heart-slowing and diuretic action of digitalis, for which it is occasionally substituted—with which it is more frequently given as an adjuvant. As a slightly depressing expectorant it is a common ingredient of cough-preparations. Large doses (from 6 to 12 grains) occasion vomiting and purging.

ADMINISTRATION.—Squill is difficult to powder, apt to cake up when powdered, and seldom given in substance.

The following preparations are officinal: Fluid Extract (*Extractum Scillæ Fluidum*, strength, $\frac{1}{1}$), dose, one to two minims; Tincture (*Tinctura Scillæ*, strength, $\frac{15}{100}$), 8 to 24 minims; Vinegar *Acetum Scillæ*, strength, $\frac{1}{10}$), 15 to 60 minims; Syrup of Squills (*Syrupus Scillæ*), dose, 4–8 c.c. (ʒ j.—ʒ ij.). The Compound Syrup (*Syrupus Scillæ Compositus*) is rather a preparation of antimony than of Squill.

ALLIED PLANTS.—The Genera *Allium*, *Scilla*, *Drimia*, etc., are closely related to Squill and some of their species are sometimes substituted for it.

Onions and their relatives are members of the same Group.

The Order *Liliaceæ* is a very large one, furnishing many beautiful garden and greenhouse flowers, and a few useful food-plants. It is in general, however, poisonous or suspicious.

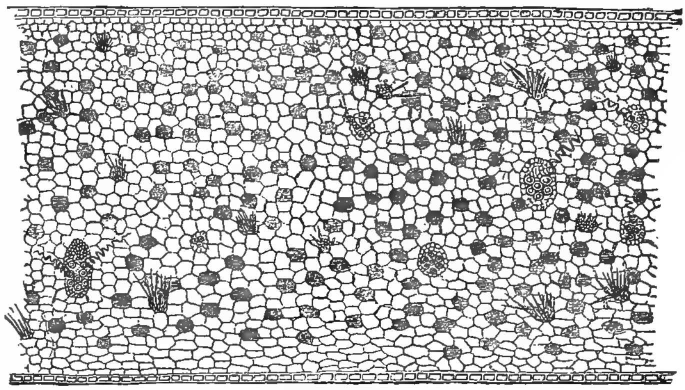

FIG. 3692.—Squill: transverse section of a Scale, magnified. (Baillon.)

The following are the most important medicines produced by this Order:

Allium sativum Linn....................Garlic.
Aloë, sp. var............................Aloes.
Veratrum viride ....American Hellebore.
Schoenocaulon officinale (*Asagræa*) ....Sabadilla.
Colchicum autumnale Linn ....Colchicum.
Etc., etc.

W. P. Bolles.

STAMMERING. Synonyms: *Lalling, Dysarthria Literalis, Stammeln, Balbutiement.* Stammering is defined as imperfect articulation of the vowel or consonant sounds, due to malformation of the organs of speech, or to imperfect innervation of the muscles employed in articulation.

Articulate speech is formed by a column of air set in vibration by means of the vocal cords in the larynx, and interrupted and varied in pitch and quality by the mouth and nasal cavity. In order to bring about these variations the tongue, lips, and palate are moved, so as alternately to open and close the passages, and in this way a very large number of sounds may be produced, which are represented by letters and called vowels and consonants. Only a small proportion of the possible sounds is used in any one language.

A continuous sound made with the air-passage open is called a vowel. The particular vowel produced depends on the position and degree of approximation of the parts during phonation.

Consonants are made with the passages more or less closed. Some of them are capable of indefinite prolongation, the air escaping either through the nose, as with *m* and *n*, or between the tongue and palate, as with *l*, *r*, and *s*. The explosives *b*, *d*, *g*, *k*, *p*, and *t*, cannot be prolonged, but there is a preliminary sound called a burr while the air is passing into the pharynx and mouth, and then the passage is opened with a flap, and takes the position of the following vowel.

No sharp line can be drawn between the two classes. The consonants *w* and *y* are made in the same way as the vowels *o* and *e*, with only a little closer approximation respectively of the lips, and of the tongue and hard palate.

Consonants are joined with the preceding and following vowel sounds. Stammering has nothing to do with the joining together of sounds, but is the inability to render them properly, even when given alone. The terms stammering and stuttering are confused, always in the older writings, often in more recent ones. The difference between them was discovered early in the present

century. Stuttering, as we shall see, is characterized by attacks of spasm varying in severity, but always of the same nature. The stutterer can render the separate sounds perfectly under favorable conditions. His trouble is only occasional, and brought on usually by the attempt to pronounce one of the explosives mentioned above.

On the other hand, stammering must be distinguished from aphasia. That has to do with neither the production nor the joining together of sounds, but with the construction of syllables and words as a whole. It is caused by the disabling of those parts of the cerebral cortex which contain the sensory or motor speech memories, or of the fibres connecting these with other parts of the nervous system.

The highest point in the cerebrum at which a lesion can cause a purely literal defect, is at the level of the corpora striata.[1] Disease above this causes impairment of the power of perception or construction of words or syllables.

Aside from occasional faulty pronunciation, to which everyone is more or less liable, there are many cases of stammering in which the trouble is due to sheer carelessness and inattention, fixed by habit. These cases are important as well from a diagnostic as from an educational standpoint, as they may be mistaken for cases of acquired speech defect, especially when organic brain disease coexists with them.

The capability of pronouncing different sounds is a matter largely of race and training. Everyone stammers in a foreign language, if he undertakes to learn its new sounds after his habits of speech are formed. Thus the German *ch*, French nasals, and Italian *r* are seldom perfectly acquired by an adult. But, according to Kussmaul, "the most choking guttural of a Swiss throat modestly retires before the vomiting throat-sounds of an Arabian."

We may divide our subject into stammering from: 1. Habit or carelessness. 2. Organic defect of the organs of speech. 3. Disease of the nerve-centres. The speech defects in all these cases may be identical, and in order to distinguish them one from the other a careful examination and attention to the history are often necessary. A complete list of sounds which may be mispronounced is not possible. It will be sufficient to indicate a few of the more common ones.

The mispronunciation of the letter *r* is called Rhotacism or Burring. This letter has the same general sound, but is produced in various ways by different nations. In English-speaking countries it is formed by approximating the sides of the tongue to the roof of the mouth, but in certain localities is often slurred. Its place is then taken by a *ŭ* or *ä* sound. In southern England it is produced by the tip of the reverted tongue. In Italy it is made by a rather prolonged and rapid vibration of the tip of the direct tongue against the palate. The Italian nobility profess to be unable to produce this sound, and use the English *r*. In Northern Germany it is made by the uvula, in Sweden by the glottis. It is evident that correct speech in one country is stammering in another; *e.g.*, the use of the uvula in pronouncing the English or Italian *r*. Again, the ordinary sound may be replaced by an entirely different one. In this case *l* or *w* is usually employed. This is regularly done by children, who acquire the *r* sound among the last.

L is often mispronounced—*r*, *d*, *t*, *y*, etc., being used instead. This is called Lambdacism. *L* should be made by placing the tip of the tongue against the hard palate, and then phonating so as to make a continuous sound, the air escaping at the sides of the tongue. If the air does not escape, the explosive *d* is produced instead; if the tongue does not touch the palate, the half-vowel *y* is made, and so on.

Lisping, or Sigmatism, is the most common form of stammering. It consists in giving *s* a wrong sound, usually that of *th*, by carrying the tip of the tongue too far forward, so as to touch the upper teeth. In this way both the hard and soft sounds of *s* are replaced. This occurs even among the Germans, who have no *th* sound in their language.

Gammacism is the mispronunciation of the letter *g*. It is sometimes hardened into *k*, sometimes changed to *d*, especially by children.

Examples of the mispronunciation of consonants might be multiplied indefinitely. Whole classes of them are changed in definite ways by different nations in learning foreign languages, so as sometimes to constitute a dialect, *e.g.*, the Scotch and Irish brogues; and, in fact, we may bring under this head many provincialisms, among them the cockney misplacing of the aspirate.

Stammering of vowel sounds consists in slurring them, so that they lose more or less of their individual character. A certain degree of this is in conformity with the spirit of the English language; in fact, many of our different vowels are, under certain circumstances, rendered in exactly the same way, *e.g.*, in bird, burn, and father, and in bun and monkey. When carried beyond the degree sanctioned by general usage, this is stammering.

Hesitating speech with interpolation of a *ŭ* sound is popularly called stammering, but usually is simply a device for gaining time.

1. All the above varieties, although they may be produced by organic causes, are often simply the result of habit. Examination then shows that the patient has always spoken in the same way, and reveals absence of other symptoms of disease; but it should be borne in mind that stammering may coexist with any disease which is compatible with speech.

Treatment here is simply an education. The patient should be carefully shown how properly to place his articulating apparatus so as to produce the required sound. Sometimes it will be found that he can readily do this when shown how. It is then only necessary to insist that he take the requisite amount of trouble every time he speaks. Other patients, especially adults, have the greatest difficulty in accustoming themselves to the change. The great point is to begin early. The acquiring of a new sound in his own or a foreign language is to an adult often an impossibility.

2. Organic defects of the organs of speech may be congenital or acquired, and lead to the same vices of articulation mentioned above, but often in a much higher degree; at the same time the voice may be changed in quality, acquire a nasal twang, etc. Here the production of the normal sounds is an impossibility, even if the patient is instructed how to do it.

Hare-lip interferes especially with the pronunciation of the labials; cleft palate, and congenital defect of the soft palate and uvula, with the gutturals, besides giving a nasal twang to all sounds.

The tongue may be bound down to the floor of the mouth by a short frænum, causing thickness of speech and imperfect utterance of the linguals.

All these conditions must be ascertained by inspection. The treatment is surgical, followed at an appropriate interval by instruction in speaking.

Excision of the tongue for cancer interferes less with articulation than might be expected; *d*, *t*, and *l* are the only sounds which are lost, and the patient is able in a little while after the operation to make himself understood.

The larynx has little to do with articulation. Disease there causes aphonia. Even after its total extirpation patients have acquired the power to speak, setting in vibration the column of air contained in the pharynx.

3. Nervous diseases may cause literal as well as other defects of speech. The diagnosis must be based on a careful review of all the symptoms. The mode of development of the stammer is of the greatest importance.

Most characteristic in this respect is the defect in bulbar paralysis. In this disease the ganglion cells in the medulla oblongata are destroyed one after the other. The process usually begins in the nucleus of the hypoglossal nerve, and extends to the facial, spinal accessory, and glosso-pharyngeal. Wherever it extends it is accompanied by a paralysis of the muscles supplied by the affected ganglion cells; and as the tongue, lips, and palate are successively involved, the sounds formed by

these parts become indistinct, and finally disappear. In this way the patient loses the power to form the linguals; paresis of the lips causes at first disappearance of *o* and *u*, later of the explosives *b*, *p*, and *d*; when the disease extends to the uvula the nasal cavity is not properly shut off, and, besides the nasal quality which is given to it, the voice becomes much weaker from the large quantity of air which escapes through the nose. At the same time the lips, tongue, and palate are paralyzed for ordinary movements to a corresponding degree; whistling is impossible, swallowing difficult, and there is marked atrophy of the muscles with reaction of degeneration (Erb). There is no true aphasia nor amnesia, but speech may finally be entirely lost by the successive elimination of its component sounds. These changes are eminently progressive in character, and usually slow. The process is then one of sclerosis. But the same symptoms may appear rapidly, from hæmorrhage or embolism. During the prodromic stage, with heaviness of speech and occasional difficulty of articulation, diagnosis is not easy.

In paretic dementia the symptoms are more complicated. The disease-process is scattered through the greater part of the nervous system. If the medulla is involved there may be much the same defects of articulation as in bulbar palsy, but they never reach so high a degree. At the same time there is apt to be marked tremor of the face and tongue, elision of syllables, loss and misapplication of words, and weakening of the logical powers. In a typical case it may be possible to make the diagnosis from the speech alone. It should be remembered, however, that stammering and stuttering may coexist with congenital mental defect and simulate this condition closely. The occurrence of delusions of grandeur and the somatic symptoms will then decide.

Multiple sclerosis may or may not cause disturbances of speech, according to the location of the areas of induration. When the cerebrum is affected it is apt to be so in the subcortical portion, and the fibres coming from the left third frontal convolution may be involved. If they are involved, they may be cut across, and aphasia will then result. Usually they persist, altered more or less by the sclerosed tissue around them, motor impulses are transmitted through them with difficulty, and speech becomes measured and slow. This is called scanning. At the same time there is irregularity in the force with which syllables are brought out. The voice is monotonous and on a high key. But areas of sclerosis may occur below the basal ganglia, and cause true stammering.

In ordinary right-sided hemiplegia speech may suffer from implication of the fibres of the knee of the internal capsule, and possibly from affection of the basal ganglia, though the latter is not proved. Clinically, when aphasia of this origin passes off there is generally left an indistinctness of articulation which coexists with partial paralysis of the tongue and lips. This is not observed with aphasia of purely cortical origin.

The treatment of these forms of stammering is simply the treatment of the disease which causes them.

Functional diseases are not often the cause of a literal dysarthria. In chorea, if the lips and tongue are affected, speech is irregular or absent during the spasm. This, however, is not the result of any disorder of the central speech-mechanism. *Henry S. Upson.*

[1] Kussmaul: Störungen der Sprache.

STARCH (*Amylum*, U. S. Ph.; Br. Ph.; *Amyli Tritici*, Ph. G.; *Amidon*, Codex Med.—also, *Fécule de Pomme de Terre*, Codex). A vegetable assimilation-product, having the composition $C_6H_{10}O_5$, occurring in nearly all phænogamous plants, and in some others in the form of solid, rounded, or peculiar-shaped, usually laminated, microscopic granules. The official starch of the above pharmacopœias is that of wheat only, *Triticum vulgare* Linn.; but, as there are several others of excellent quality, prepared on a large scale for domestic and manufacturing purposes, the above restriction, at least in this country, is not always heeded.

Starch is primarily formed, either directly, or, as is more probable, through the medium of some soluble hydrocarbon, like sugar, in the chlorophyll corpuscles of the leaves and green parts of plants, by the aid of sunlight, from the carbon dioxide of the air, and water. It is one of the steps in plant-assimilation. The granules first appear in these corpuscles as exceedingly minute, trans-

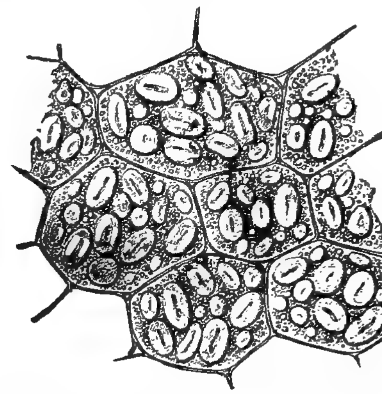

FIG. 3693.—Section of Seed of Vetch, *Vicia Sativa Linn.*, showing rounded granules of starch in cells otherwise filled with granular nitrogenous substance. $\times \frac{140}{1}$.

parent particles; as they grow they may remain within the starch-forming corpuscle, or they may rupture and protrude from it. The starch does not remain long, nor does it become fully developed in size and markings in these growing parts of plants, but, becoming changed to a soluble form (sugar, dextrine, etc.), passes down through the

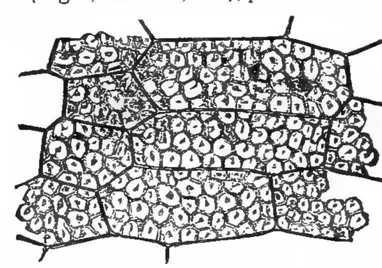

FIG. 3694.—Section of Seed of Maize, showing almost solid masses of polyhedral starch-granules completely filling the parenchyma.

cells and is consumed by the growth of stems, roots, etc.; that which is not wanted for immediate use being again transformed to solid granules in some quieter and more suitable organs, like pith (sago), rhizome (arrow-root), or in specially developed parts designed for storage in large quantities, like tubers (potatoes), fruits, and seeds (the

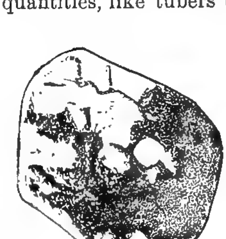

FIG. 3695.

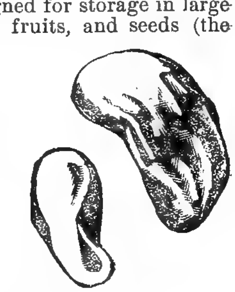

FIG. 3696.

FIGS. 3695 and 3696.—Granules of Potato Starch swollen by Boiling; those shown in Fig. 3696 afterward shrivelled as they cooled, or they may have lost some of their contents.

cereal grains, buckwheat, etc.). In these more permanent reservoirs the accumulation may be so dense as to crowd out all other cell-contents, or even to make the granules angular and polyhedral by pressure against each other. Figs. 3693 and 3694, copied, like all the others in this article, from Berg's "Atlas zur pharma-

ceutischen Waarenkunde," show the extent to which this crowding is carried.

General Description and Chemistry.—With the exception of some doubtful substances of scientific interest only, starch always occurs in granules of microscopic size, the largest (*Canna, Tous les Mois*) barely

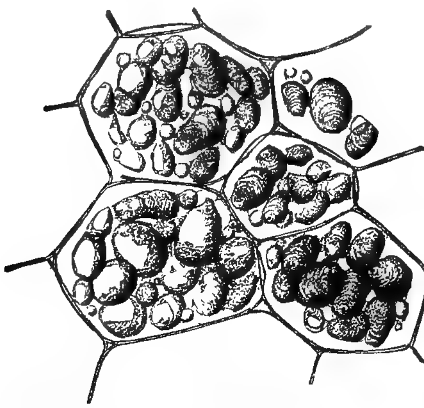

Fig. 3697.—Bit of Cellular Tissue from the Potato, showing very numerous loose starch-grains and very thin-walled parenchyna. × 190.

visible to the naked eye, the smallest (rice) the ten-thousandth of an inch in diameter. The granules are hard, highly refracting, of rounded, oblong, or peculiar outline, uniform or characteristic in each plant. If large, they almost always show a series of concentric lines or shades around a spot called the hilum, which may be

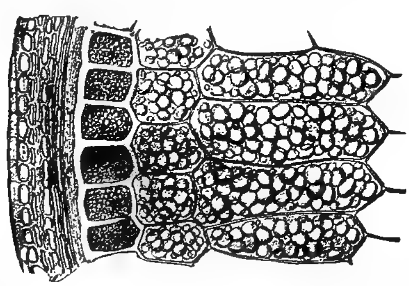

Fig. 3698.—Transverse Section of Wheat, with closely packed starch-granules, cuticular layers, wall of ovary, etc. × 190.

central, or more or less excentric. When dry, the hilum in many varieties season-splits and presents a variable stellate, branching, or single fissure, which, holding air when the starch is immersed under the microscope, looks black. Under polarized light in the microscope a dark cross, formed by two intersecting lines meeting at the

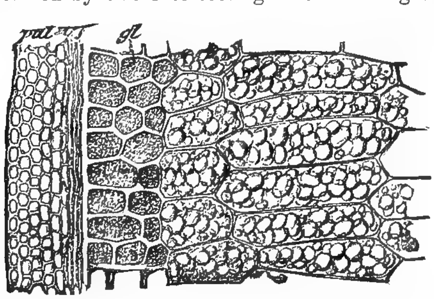

Fig. 3699.—Portion of Transverse Section of Barley; *pal*, husk (? spelye); *gl*, gluten-cells; *l*, pericarp; *T*, seed-coat. × 190.

hilum, gives starch a very characteristic appearance. Cold water has little effect upon starch, further than to make its rugæ a little less prominent, unless the granules have been triturated with sand to cut them to pieces, when a little is dissolved by it; but when heated in water to, say, 140° or 150°, the granules swell, lose their characteristic outline, and become less refracting to light; if the heat is carried still further the action upon polarized light is lost, and before the boiling point is reached they burst and form an opalescent granular mass (starch paste) in which some shreds of sac and tissue can usually be seen.

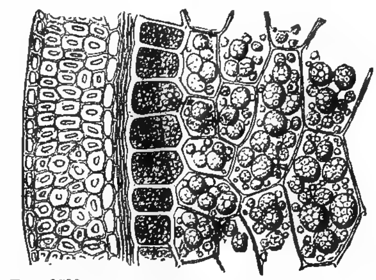

Fig. 3700.—Transverse Section of Oats, showing composite granules. × 190.

Starch of all plants has essentially the same chemical composition and reaction ($C_6H_{10}O_5$ or $C_{36}H_{62}O_{31}$, according to Nägeli). It is white, odorless, or nearly so, tasteless, becoming finally sweetish in the mouth from partial change; insoluble in alcohol and ether; boiled with about ten parts of water it gives a moderately stiff, bluish, translucent jelly or mucilage. Treated with a minute quantity of iodine, it is turned to an intensely blue color, which can be discharged by heat, returning again upon cooling.

Starch is not a homogeneous substance, but consists of at least two constituent parts, one more soluble than the other, called granulose; the other, which comprises the skeleton of the granule, is more like cellulose itself. Treated with diluted acids, heat, diastase, or one of a number of other vegetable or animal ferments, starch is converted into dextrine, a substance in extensive use as a mucilage or size; and finally into grape-sugar or glucose, which is now made from it in great quantities, as a substitute for sugar in cheap confectionery, etc.

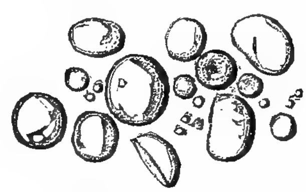

Fig. 3701.—Wheat Starch.

Preparation.—Figs. 3693 and 3694, as well as Figs. 3697 to 3700, will show how closely the starch is entangled with cellular structure, and other products of vegetable growth. The problem is to separate it and get it as completely clean as the succeeding figures (Figs. 3701 et seq.) show it.

This is generally accomplished by grinding and washing; for arrow-root, for instance, the pulpy rhizomes are cleaned with care and ground, then the pulp is washed over sieves; when the starch flows through with the water, it is allowed to settle, and then washed again and again until the soluble matters and the tissue are completely washed away. Sago pith is treated in essentially the same way. Potatoes are ground to a pulp and allowed to stand until the mucilaginous matters are disintegrated by decomposition, then washed as above. From wheat the starch is washed out of the glutinous dough, made by mixing a coarsely ground meal with a little water; this may be kneaded under a stream over a sieve, or it may be put in large bags and rinsed and pressed until the starch is all washed out from the gluten. The processes, of which this is the merest outline, have considerable variety in detail and in the machinery and conveniences used.

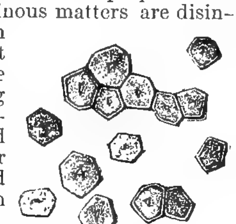

Fig. 3702.—Maize Starch.

Varieties.—The only certain means of determining from what source a given specimen of starch has been derived is to examine it microscopically, when the size, shape, markings, and other visible peculiarities of the granules will generally suffice to make it certain. The

following characteristics of the commoner kinds are magnified uniformly three hundred and fifty diameters.

1. *Wheat Starch* (*Amylum*, U. S. Ph., etc.). "In irregular, angular masses, which are easily reduced to powder; white, inodorous, and tasteless; insoluble in ether, alcohol, or cold water; under the microscope appearing as granules, mostly very minute, *more or less lenticular in form, and indistinctly, concentrically striated.* Triturated with cold water, it gives neither an acid nor an alkaline reaction with test-paper. When boiled with water it yields a white jelly, having a bluish tinge which, when cool, acquires a deep blue color on the addition of test solution of iodine" (U. S. Ph.). The only part of this description characteristic of wheat starch alone is that which is italicized. The granules average about 0.050 millimetre in diameter.

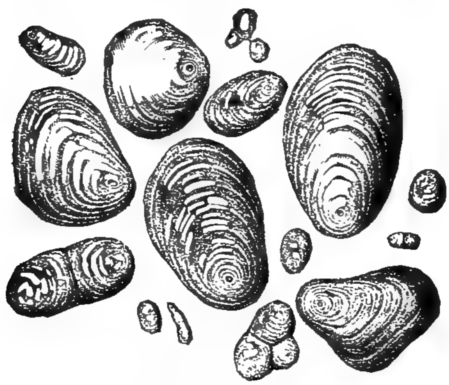

FIG. 3703.—Potato Starch.

FIG. 3704.—Arrow-root.

2. *Maize*, or *Corn Starch*, is smaller than the preceding, about 0.030 mm. in diameter, of polyhedral form, with central hilum.

3. *Rice Starch* resembles maize starch, but is very much smaller.

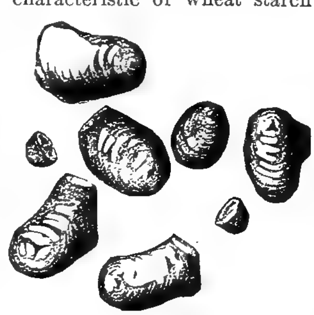

FIG. 3705.—Sago.

4. *Potato Starch* consists of two classes of granules mingled together—fine spherical ones, from 0.01 to 0.03 mm. in diameter, and large ovoid ones with very excentric hilums and very distinct *rugæ*, recalling oyster or clam shells, from 0.14 to 0.18 mm. long.

5. *Arrow-root* is finer than potato starch, which it somewhat resembles; the granules are more spherical, with blunter, thicker ends, very distinct excentric fissures, and less distinct *rugæ*. Canna starch, a variety of arrow-root, has enormous granules, nearly twice as large as those of potato. Neither of these varieties has the small forms of that from potato.

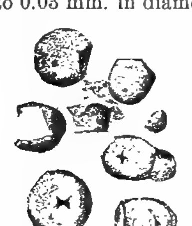

FIG. 3706.—Tapioca.

6. *Sago* has medium-sized (0.04 to 0.07 mm.), oblong, rather irregular, often faceted, sometimes shoe-shaped granules, with excentric hilum and pretty distinct *rugæ*. The sago of commerce is often half-cooked, with many of the granules destroyed.

7. *Tapioca:* spherical, medium-sized granules, with large facets; commercial tapioca is also partly cooked.

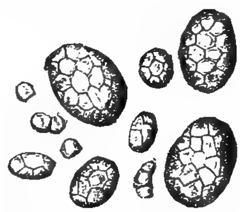

FIG. 3707.—Oat Starch.

Besides the above are the starches of numerous familiar grains and roots, which are not separated for sale or use, but which are of interest in detecting adulterations, mixtures, etc., or in identifying the powders of drugs. The three accompanying cuts will serve as illustrations of this large class.

Medical and Surgical Uses of Starch.—This substance can in no sense be called a medicine, as it is absolutely without physiological action. It is the type of crude carbonaceous or non-nitrogenous food, and its conversion into sugar in the mouth and intestine is one of the elementary facts of digestive physiology. As a toilet powder the finer varieties—rice and corn starches—are in universal use, and one or other of these is the foundation of most of the proprietary powders.

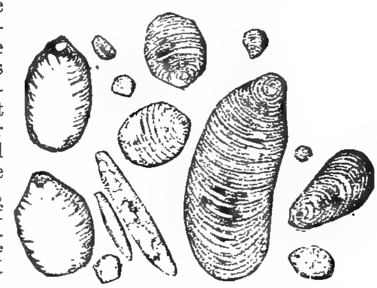

FIG. 3708.—Turmeric Starch.

Boiled starch, and especially the flours of starchy substances, are frequently used as poultices, but they are not so convenient and suitable as the mucilaginous flours of linseed and slippery elm.

Starch mucilage is occasionally used for immovable bandages, but it is less adhesive and less suitable for this purpose than flour-paste, glue, dextrin, silicate of potash, or plaster-of-Paris. One part dissolved glue, as prepared for cabinet-makers' use, and two or three of starch mucilage, a little thinner than the laundress uses it, mixed and applied hot, make a most excellent combination for such bandages—light, very stiff, and agreeable in color.

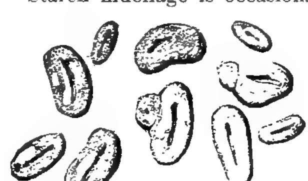

FIG. 3709.—Vetch, or Lentil Starch.

There are two officinal preparations of starch: the Glycerite (*Glyceritum Amyli*, U. S. Ph., ten parts of starch dissolved in ninety of hot glycerine), is a permanent translucent jelly, useful in moistening pill masses, for emulsions, and similar purposes. Iodized Starch (*Amylum Iodatum*, U. S. Ph.) is rather a preparation of iodine. It is made by triturating five parts of iodine with ninety-five of starch, with the aid of a little water. It is a blue-black powder, and a suitable preparation to administer for free iodine if it is desired to give that drug internally. Starch is related, pharmaceutically, to the mucilages, chemically to sugar. *W. P. Bolles.*

STATE MEDICINE. John Simon, C.B., F.R.S., for many years chief officer of the Local Government Board of England and Wales, says in a report made in 1874. "In my recent Annual Report the vast amount of injury which is suffered day by day in this country through diseases well known to be preventable, was referred to, in regard to the duty it imposes on all who have undertaken to serve in the new sanitary organization of the country, and I submitted that the Local Government Board, viewed as a Central Board of Health, and the more than fifteen hundred district authorities which,

each with its medical officer of health, locally administer the health laws, may be regarded as having had their respective functions assigned to them in special and systematic relation to that state of things." [1]

Professor Loewenthal, of Lausanne, gives as his third division of instruction in hygiene: "L'enseignement particulier pratique, destiné aux médecins qui aspirent aux postes d'application de l'hygiène, . . . tels que ceux des médecins attachés aux services sanitaires publics (municipaux ou de l'État);" and a recent American writer on the functions of Government says, that "it is the business of Government to do for the mass of individuals those things which cannot be done, or cannot be so well done, by individual action."

In these three quotations we have well set forth, from the theoretical, educational, and practical stand-points, the comprehensive character of the work which, in those countries where the functions of Government have been most progressively developed, is included under Public Hygiene, or, what is better designated, State Medicine. In articles found elsewhere in the HANDBOOK, as Sanitary Inspection, Sewerage, Quarantine, Food Adulterations, have been discussed some of the principal subjects included properly within the scope of State Medicine; quarantine, as generally understood, being a function of General Governments; sewerage and sanitary inspection that of Municipal or Local Governments; while the detection of food adulterations is usually in part performed by General Governments and in part by municipal authority.

It is evident that, whatever theory might indicate as to the duties peculiar to a General Government, on the one hand, and to municipal authorities on the other, the form of government—whether it be an autocracy, such as Russia, or a democracy, as Switzerland or the United States—will be a primary factor in determining the extent to which the term *State Medicine* will have any distinctive meaning or importance. Our personal conception of what should properly be included under the term has grown out of a practical experience of some years, and is derived wholly from the stand-point of results obtained, and quite apart from any preconceived theories. *Whatever system is found to save to the State the largest number of useful lives (in esse or in posse, e.g., workers or the children of our communities), and which further nurtures and maintains them in the best possible condition of physical, intellectual, and moral health is the best system.*

From this definition it will at once appear that in our opinion the function of Government is to make such enactments as will give ample powers to central authorities to maintain efficient quarantine systems, both internal and external; to endow such institutions as will supply the necessary education in practical hygiene to medical health officers, sanitary engineers, etc., and to establish laboratories wherein those scientific investigations which appertain to the discovery of the causes of disease, and to the measures to be taken for their limitation and prevention may be carried on. At the instance of the central authority must further be enacted such legislation as shall clothe municipal or district authorities with ample powers for the isolation of those suffering from contagious diseases, and for the institution of such works—sewerage systems, public water-supplies, regulations for the construction of buildings, etc.—as shall conduce to the maintenance of the public health in the highest possible degree. Finally, it comes very naturally within the scope of State Medicine to encourage the teaching in all schools of those principles which regulate the life of the individual, as regards either personal conduct or the regulation of the home, in those matters which bear most directly upon the preservation of health, and in some instances upon its improvement.

Having, in general terms, outlined the scope and province of State Medicine, we may state, what at once is apparent, that climate, aggregations of people, occupations, etc., will determine to what extent the functions of the State shall be exercised in order to conserve the highest interests of the people. From what has been witnessed in the past, it is plain that legislation, at first sight often seemingly opposed to some individual interest, may be expected to fall, in many respects, short of what the needs of the general community demand; but clear conceptions of what is required, and persistent efforts to make the public realize wherein their highest interests consist, are necessary before legislation is likely to supply the facilities for real progress in State Medicine.

It would be of interest were we to give a history of the advances of State Medicine, and the degree in which the principles already laid down have been carried into practical effect in different countries; but the still crude condition of State Medicine in many countries would detract very much from any practical value appertaining to such a statement, even did space permit. Our purpose will, we judge, be equally well served if we indicate the scope of State Medicine in those countries where it has reached its highest state of development. It is everywhere readily conceded that in State Medicine, in so far as regards its practical application to the ordinary conditions of society, England has, up to the present, been in advance of all other countries; and further, that the scope of the work of the Local Government (Central) Board is wider, and the relations existing between the Central Board and Municipal Sanitary Authorities are closer and better defined, than in any other English-speaking community. Since the cholera years 1848–53, there have been framed various Public Health Acts, in which have been developed to a considerable degree the principles already enunciated. These Acts are consolidated in the English Public Health Act of 1875. The whole of England and Wales is divided into urban and rural sanitary districts, governed respectively by urban and rural sanitary authorities. An Urban district is either a borough under the supervision of the mayor, aldermen, and burgesses, acting under direction of the Council, or an Improvement district under Improvement Commissioners, or a Local Government district under its Local Board of Health.

A Rural Sanitary District is an area not included in any of the foregoing, and the guardians of the union (Poor Law Guardians) form the rural authority of such a district. Over the Local Sanitary Authorities there is the Local Government Board, which has supreme control in many respects in matters relating to the public health. London City does not fall within the operations of the General Act. Local Sanitary Authorities are elected by the people for terms of three years, and have all necessary powers to levy rates for necessary sanitary improvements, and in those cases where continued neglect to protect the public is evident, the Central Board can require public works to be undertaken by the municipality. Similar central powers to some extent exist in France; but in few countries does this general control by the central authorities extend to matters other than enforcement of measures for the control of outbreaks of contagious diseases.

As regards the present position of State Medicine in the United States, it may be said that to the American Public Health Association, a non-official body, though including most prominent Federal and State sanitary officials, is due in large measure such progress as has been made during the past fifteen years; and that, as a result of its persevering efforts during an epidemic of yellow fever of unwonted extent and severity, was established, in 1878, the National Board of Health, a body appointed, and supplied with grants, by the Federal Government. Since 1882, the money grants which had enabled the Board to institute investigations of great interest and importance regarding the causation of disease, etc., have, through political prejudice, been in great part withheld, and but little practical work has been done by it; but there is reason to suppose that this anomalous state of affairs will soon be remedied. In the meantime, to the Marine Hospital Service has been committed the protection of the country against foreign outbreaks of disease, in so far as the Federal Government is concerned.

A limited amount of experimental work in the field of bacteriology is still carried on under the auspices of the National Board of Health; but work such as that done by the Governments of England, France, and Germany

is conspicuously limited in amount. The field of contagious animal diseases is in a much more advanced state, controlled as it is by the Bureau of Animal Industries, under the Department of Agriculture.

In keeping with State autonomy the State legislatures have done, in some instances, a considerable amount of sanitary work. With a few exceptions all the States of the Union have State Boards of Health, varying greatly in their powers and status.

In some instances these organizations are crude, with limited funds and equally limited powers. Indeed, the control which State Boards have over Municipal Health Boards is of the most limited character, being little more than advisory. The Local Boards, which by some State enactments (*e.g.*, those of New York State) are compulsory, have in a few instances statutory laws comprehensive and uniform in character under which action may be taken. Their work is done almost wholly under municipal by-laws, which are naturally of the most varied character, as regards both the extent and the thoroughness of their execution. In some instances (as in New Jersey) State Boards have control of animal diseases; while in others (as in Illinois) they are Boards for the Regulation of the Practice of Medicine; and in others, again (as in New York), for the registration of births, marriages, and deaths. In Massachusetts practical laboratory investigations have, to some extent, been carried on from time to time by the State Board. The first State to make such investigations systematically is the State of Michigan, where a hygienic laboratory is being erected at Ann Arbor, at a cost of $30,000, with an additional $5,000 for its equipment. The staff will consist of a professor of hygiene, and an assistant professor. There will be a course of lectures by the Professor of Mechanical Engineering on "Heating and Ventilation," by the Professor of Civil Engineering on "Sewerage Systems," and by the Professor of Law on "Public Health Laws." Special laboratories for the various branches of the work will be established. The main object of the laboratory, as stated in the memorial asking for its establishment, is to conduct original investigations into the causation of disease. This new department, added to the very efficient work of the State Board in other matters, will place Michigan in the van of progress as regards State Medicine.

In Canada, State Medicine is in a position which compares favorably with that in the United States. With two exceptions all the provinces have some form of State organization, while the Federal Government, by the Act of Confederation, has charge of quarantine, vital statistics, and food adulterations. In many respects the provincial statutes are modelled after English Public Health Acts. For instance, in the Province of Ontario, the most advanced in State Medicine, there is a Central or Provincial Board, whose duties and powers are defined by statute, and to it are given powers for investigating matters bearing upon the public health, and very complete facilities for acting promptly and effectively in threatened or actual outbreaks of contagious disease, whether occurring as a danger from without or from within. The Provincial Board has ample power, in accordance with statutory by-laws, to compel action to be taken by Local Boards, whose organization is compulsory, when contagious disease occurs in their municipality. It also requires the submission to it of all schemes for the establishment of public systems of sewerage and water-supply. So far very little experimental sanitary work has been done in Ontario, there being no special facilities enabling the Board to undertake such work. A special staff of medical health officers and sanitary police, under the direct control of the Provincial Board, has, in time of need, been organized to limit and suppress epidemics of disease likely to get beyond the control of individual municipalities. In other Provinces larger districts are assigned to medical officers, who act during epidemics, while elsewhere, as in many States, municipal councils have powers as health officers assigned to them.

That part of State Medicine which deals with practical instruction in this science has, in Europe, been prosecuted in varying degrees in different countries. To such work as that carried on by Parkes, Klein, Creighton, Sanderson, Baxter, Smith, and others in England; to the investigations of Pasteur, Chauveau, Duclaux, Chamberland, and others in France, and to the bacteriological investigations of Koch, and the chemical studies of Pettenkofer in Germany, are we to attribute the present position of practical knowledge of hygiene. In some countries the instruction in public hygiene is of a limited character, being confined to a course of hygiene in some medical school. In others there are institutes of hygiene on the most extended scale, as, for instance, at Munich, Leipzig, and Copenhagen. In Hungary the province of instruction in State Medicine is of an extended character. M. Trefort, the Hungarian Minister of Education, expresses the view that hygiene should be taught in all secondary or high schools, and that it can only be properly done by medically trained hygienists. He has, therefore, created in the medical faculties a special course of instruction for physicians aspiring to the position of professors of hygiene for secondary schools. At Pavia and Turin, in Italy, and at Charcow and Moscow, in Russia, are important hygienic laboratories; and Stockholm has an excellent institute of hygiene, established at a cost of 20,000 francs.

The reader will perceive, from the illustrations here given, that these State organizations were originally started with the object of limiting outbreaks of contagious disease. They employed first, of course, the crude methods then in use, but have gradually improved upon them as a result of much scientific and experimental work. State Medicine was a creation of necessity in times of public danger, but its future development will be in proportion to the scientific character of its work, and to the appreciation on the part of the public of the economic and beneficent results of such work.

Peter H. Bryce.

STAVESACRE (*Staphisagria*, U. S. Ph.; Staphisaigre, Codex Med.). The seed of *Delphinium Staphisagria* Linn.; Order *Ranunculaceæ*. This is a showy annual or biennial herb, arising from a stout, tapering root, by an upright, branching, hairy stem, about a metre high. Leaves alternate, on hairy petioles, and themselves pubescent or hairy beneath; the lower long-stemmed, of from seven to nine spreading, lanceolate lobes; the upper more and more simple; those of the inflorescence small, sessile, and simply lanceolate. Flowers irregular, large, in open racemes or panicles, about two centimetres across; calyx of five petaloid sepals, the three upper erect, the middle one spurred at the base, the two lateral ones broad, rounded, and spreading. Petals four, the two upper narrow, erect, sending spurs into that of the upper sepal; the two lower rounder. Stamens numerous; carpels three, ten-, or twelve-ovuled. Sepals and petals pink or purple, the former tipped with green. Seeds pyramidal, four-sided, slightly curved, about half a centimetre long; brownish-gray externally, white and oily within, odorless, but bitter and acrid.

This plant is a native of the South European countries, Asia Minor, etc., and is also cultivated. The seeds are imported from the south of France and Italy. They were known to the ancients, and for twenty centuries have been used for about the same purpose as at present —killing pediculi and similar vermin.

Composition.—The seeds contain about twenty-five per cent. of a non-drying *fixed oil*, and about one per cent. of alkaloids, of which the following have been isolated and named: *Delphinine*, in fine, large crystals; *Staphisagrine*, amorphous; *Delphinoidine*, also amorphous; and *Delphisine*, in crystalline tufts. Of these, the first is the most important and active, the second least so, while the third and fourth resemble the first, but are weaker.

Action and Use.—Stavesacre is an active and poisonous drug, irritant to the skin and mucous membranes, causing itching, stinging, burning, sneezing, etc., as well as diarrhœa and vomiting. Of the alkaloids, Delphinine best represents it; rubbed into the skin it causes local inflammation, on the tongue burning and numbness, in

the stomach nausea and distress, and, when absorbed, cardiac and respiratory slowing, diminished spinal irritability, and sometimes mental disturbance. The others resemble delphinine, but are less intense. Delphinine reminds one of both aconitine (to which it is botanically related) and veratrine. Staphisagrine is somewhat peculiar; it is not very active, but appears to resemble curare in its action upon striped muscle.

Neither the crude drug nor its alkaloids are given internally, so its exact action has but little practical bearing. It has from a remote time been employed, either by itself or in ointments or other vehicles, solely for the purpose of killing pediculi, and related animal parasites, on man and animals. At the present time it is mostly consumed in veterinary practice, kerosene or petroleum, petrolatum, sulphur, and *unguentum hydrargyri* taking its place in human medicine. An ointment can be made with twenty per cent. or so of the powdered seeds, or with from one-half to one per cent. of the alkaloid.

Allied Plants.—The beautiful genus contains the Larkspurs, many varieties, and is closely related to the equally beautiful Aconites. For the order, see Aconite.

Allied Substances.—Sabadilla is another time-honored parasiticide of very similar properties to the above, and is used in the same way. Kerosene and petrolatum are put to the same uses. *W. P. Bolles.*

STERILITY IN THE FEMALE. Synonyms: Barrenness, infertility; Lat., sterilitas matrimonii; Fr., stérilité; Ger., Unfruchtbarkeit.

Sterility in the female implies an inability to bring forth a living child. It involves two points for consideration: First, her inability to conceive at all; and second, her inability to complete successfully the period of gestation. Many women never conceive at all. Many other women conceive, but are unable to complete the period of gestation.

Women who never conceive are said to be *absolutely* sterile. Women who have borne one or two children and do not conceive thereafter are said to be *relatively* sterile.

Etiology.—Several organs are involved in the process of genesis in the female. The essential element of this process is the ovum, which is supplied by the ovary. The ovum is conveyed from the ovary through the Fallopian tube to the uterus, where it meets the spermatozoa, and genesis follows. The semen reaches the uterus through the vagina. Consequently, the question of sterility involves the investigation of the condition of, 1st, the ovaries; 2d, the oviducts; 3d, the uterus; and, 4th, the vagina. In addition, upon the *general condition* of the patient alone non-conception often depends. Under this head may be classed the extreme gouty vice, the syphilitic taint, anæmia, great obesity, chronic alcoholism, and spasmodic dysmenorrhœa.

The Ovaries.—1. The investigation of the ovaries in sterility includes inquiry into the possibility of the absence or of the imperfect development of these organs, conditions rarely met with excepting when the other sexual organs are anomalous.

2. Inflammation, chronic or acute, of the ovaries may result in such adhesions of the organs that the ovum is totally prevented from entering the oviducts. It may lead to arrest of function, so that the ovum can no longer be matured. The ovary may become so embedded in inflammatory deposit that extrusion of the ovum from its capsule is no longer possible.

3. Structural degenerations of the ovary may exist, *e.g.*, cystic, carcinomatous, and sarcomatous, and are generally attended with sterility.

4. Displacement of the ovary, often attended with chronic inflammation, may place it beyond the reach of the fimbriated extremity of the Fallopian tube so completely that the ovum cannot be transmitted to the uterus.

The Fallopian Tubes.—1. Absence or defective development of the oviducts is usually associated with other abnormalities of the sexual system, and causes hopeless sterility.

2. Inflammation of the oviducts is a cause of sterility. It may affect the serous coat, resulting in such fixation of the tubes as to prevent the *morsus diaboli* from coming in contact with the ovary, or in constricting bands that occlude the calibre of the tube. It may attack the mucous lining of the canal, and result in the production of secretions which are destructive to the spermatozoa or the ova, or it may result in permanent occlusion of the opening of the tube, whence may follow collections of blood, pus, or serum. In either case the ovum is prevented from descending to the uterus, and sterility follows.

3. Degeneration of the tubal structures produces a hopeless occlusion of the canal, and thus causes sterility.

The Uterus.—Defective development of the uterus assumes various forms, such as its total absence, its undersize, or its abnormal lateral growth into either a unicornus or a bicornus uterus. Conoidal cervix, with the commonly attendant stenosis of the os, may be classed as one of the variations of defective development. The last-mentioned condition constitutes one of the most frequently removable causes of sterility.

Degenerations: 1. Myomata often cause infecundity, but they are not always a barrier to conception. The coexistence of this degeneration and of pregnancy constitutes one of the most serious conditions encountered by the obstetrician.

2. Sarcomata seem always to prevent pregnancy.

3. Carcinomata, if extensive enough, cause sterility. In their early stage conception is often possible, and is now and then encountered.

Abnormalities of involution: An excessive involution (hyperinvolution) or a deficient involution (subinvolution) often constitutes a barrier to conception. The writer recently saw a healthy patient, aged twenty-seven, who bore a child at twenty-one years of age, and had not menstruated since that event. The uterus measured but one and one-fourth inch in depth. The organ may be still further decreased in size, even to a quarter of an inch.

Subinvolution of the uterus is often accompanied with an inflammatory state, completely preventing the occurrence of pregnancy.

Inflammation of the uterus or the circumjacent tissues is a very common cause of sterility. The morbid process, according to its seat, may be endocervicitis, endometritis, metritis including cervicitis, parametritis, or perimetritis. Often two or more of these conditions coexist, and render the cure very tedious. Endometritis may be accompanied by abnormal secretions destructive to the spermatozoa, there may be a dilated uterine cavity, the lining membrane of the uterus may be made so unhealthy that it becomes impossible for a fertilized ovum to secure a lodgement thereon, or the inflammation may cause more or less occlusion of the uterine orifices.

Displacements: Malpositions of the uterus include prolapse, flexions (retroflexion, anteflexion, and lateroflexion), and versions (anteversion and retroversion).

Anteversion and anteflexion exist most frequently in nulliparæ. Retroversion and retroflexion exist most frequently in those who have borne children. Lateroversion and lateroflexion are present when an inflammation has existed in either broad ligament, resulting in shortening of the ligament, or when some foreign growth or an inflammatory deposit exists on the side of the pelvis opposite to the displacement, crowding the uterus away from its normal condition.

The Vagina.—This organ may be so injured or may become the seat of discharges so fatal to the semen that it becomes a source of sterility.

Malformations: The vagina may be absent congenitally. Its occlusion is very rare. A severe vaginitis has been the cause of an almost total occlusion by the agglutination of the vaginal walls. The hymen is sometimes so hypertrophied that it becomes a barrier to copulation. Unnatural shortness of the vagina renders it incapable of retaining the semen a suitable length of time.

Inflammation: Vaginitis nearly always produces discharges fatal to the semen. It is occasionally productive of that condition of spasm called vaginismus, but this may also be caused by other conditions.

Injuries: Extensive perineal lacerations often become causes of sterility. Fistulæ may also prevent conception.

Degenerations: Elephantiasis labiorum prevents coitus, and thus becomes a barrier to insemination. Extensive urethral caruncle often interferes with successful intercourse.

General State of the Patient's Health.—An indefinable something in the patient's general condition is oftentimes the apparent cause of a sterility. The proof of this statement consists in the fact that women, sterile when in poor health, often conceive when their general condition has been improved by remedies, by change of climate, or by travel. Some women are sterile because of the presence of discharges from the genital tract which have their origin in a systemic taint. The lithæmic state, for example, may give rise to such discharges, which cease when an anti-lithic course of treatment has been followed, and conception thereafter may follow. Many cases of sterility of this form have been wholly removed by a course of treatment at suitable mineral springs.

Under this head may be also mentioned that variety of sterility which is dependent upon some obscure incompatibility of the parties, illustrations of which every physician of experience has encountered. A woman, sterile in many years of married life, who has been, for this reason, abandoned by her husband, eventually secures a divorce, is married to a second husband, and bears a number of children. The old illustrations of Augustus and Livia, and of Napoleon and Josephine, are quoted by writers on sterility.

Diagnosis.—It is not always that only one of the foregoing obstacles to conception is present. Very often two or more of them coexist. When the causes of sterility are manifold in the same patient, it is obvious that the skill of the gynæcologist will often be taxed in recognizing and removing them. A complete diagnosis can be arrived at only by an exhaustive examination. It is always a safe plan for the physician to endeavor to find all the possible causes of sterility in each patient.

It must be confessed that only too often does it occur that, after every discoverable removable obstacle to conception has been corrected, sterility will still exist.

Prognosis.—In no condition is the prognosis more uncertain. In a general way, it may be stated that imperfect development or marked malformations constitute an absolute bar to conception.

In the same manner, it may be stated that removable obstacles to conception, as inflammations, flexions, versions, stenosis, some vaginal occlusion, or fistulæ, may be treated with a fair prospect of fruitful results. The apparently complete removal of these obstacles, however, only too often fails to render the woman fruitful.

Treatment.—A successful treatment of sterility in the female is secured by removal of all the obstacles to conception. Such treatment does not include that of sterility in the male, although many gynæcologists investigate the male first, since about one case in ten of infecundity in marriages has its origin in the male. With this branch of the subject, however, the present article has nothing to do.

After the physician has discovered as many obstacles to conception as he can find, he must set about removing them. Insufficient treatment nearly always results in failure. In no department of gynæcology is more persistence in treatment demanded.

Urethral caruncles, vulvar vegetations, and other sensitive excrescences must be removed or destroyed.

Vaginal stenosis or contraction must be stretched and the canal must be kept patulous.

Cervical stenosis must be overcome by sea-tangle or tupelo tents, or by stretching with dilators. Division of the cervix by the hysterotome has been much practised successfully in the past, but is at present falling into disuse, forcible dilatation being preferred.

Uterine deviations must be corrected. Versions can often be rectified by suitable pessaries. It has been suggested that anteversion may be corrected by allowing the bladder to become distended with urine, thus pushing the fundus uteri backward and throwing the cervix sufficiently forward to place the os in a direct line with the seminal ejaculation, thus facilitating the entrance of semen into the cervical canal. Similarly, retroversion, it is alleged, may be temporarily corrected by allowing the rectum to become distended with fæces, whereby the fundus uteri may be crowded forward.

Flexions demand the use of the intrauterine stem-pessary.

Hyperinvolution may be treated with the galvanic intra-uterine stem-pessary. Similarly, attempts may be made to stimulate the growth of an imperfectly developed uterus.

Inflammations must be treated *secundum artem.* Various antiphlogistic methods of treatment are in vogue. Cauterizing applications, hot-water douches, glycerine tampons, the dry treatment of Englemann, etc., each has its adherents.

Morbid growths on the endometrium must be removed or destroyed.

Quite exceptionally, the method of introducing semen into the uterus by means of a syringe and a tube has been used. it is alleged, successfully.

In the treatment of all cases of sterility the physician must never ignore the general condition of the patient. Systemic vices must be eradicated as far as possible. Many cases of sterility can be cured by general treatment. Repeated abortions indicate the possibility of the syphilitic taint. The existence of this vice in a marked degree is an almost certain obstacle to the chances of gestation being completed, and it must, therefore, receive continuous and persistent treatment for a period of at least two years. *J. H. Etheridge.*

STERILITY IN THE MALE. This term, in its accepted sense, implies inability to impregnate the female, from other causes than that of impotence or loss of the power of copulation (see Impotence). "Sterility not only does not include impotence, but is met with in subjects who are vigorous in intercourse, and who may ejaculate a fluid which, in the absence of minute examination, presents all the properties of normal semen. Sterility includes, first, azoöspermism, or the condition in which either no semen whatever, or unproductive semen, is secreted; secondly, aspermatism, in which spermatic fluid is not ejaculated; and, thirdly, misemission, or the failure to deposit fertile semen in the upper portion of the vagina. In the first variety intercourse and ejaculation are natural, but the essential anatomical elements are absent or dead, either because they are not formed, or are imprisoned behind an obstacle seated in the epididymes or vasa deferentia, or because they are unable to live in the medium in which they are suspended. In the second variety the ability to copulate is unimpaired, but the power to ejaculate is prevented by an impediment situated between the seminal vesicles and the urinary meatus In the third variety coition and emission are perfect, but fruitful semen fails to reach its proper destination in consequence of congenital deficiencies of the urethra, or of fistulous openings in that canal, resulting from inflammation, or of abnormal positions of the meatus" (S. W. Gross, "On Impotence, Sterility, and Allied Disorders of the Male Sexual Organs." Philadelphia, H. C. Lea's Son & Co., 1883).

1. *Azoöspermism* may be due: *a.* To congenital bilateral absence of the testes, or congenital bilateral deficiency of the epididymes or vasa deferentia. Such absence of the testes likewise results in impotence and may here be dismissed. Such deficiency of the excretory apparatus of the testes need not result in impotence, but prevents all escape of spermatozoa.

b. To non-descent of the testes into the scrotum. Individuals thus affected are potent; they are usually sterile, but may, in exceptional cases, be fruitful (S. W. Gross).

c. To affections of the testes. Bilateral atrophy, from whatever cause, always diminishes, and sometimes prevents, the formation of spermatozoa. Simple parenchymatous orchitis results in absolute azoöspermism. Partial destruction, by malignant or other new-growths, does

not necessarily result thus. After syphilitic orchitis spermatozoa may return under proper treatment.

d. To bilateral obliteration of the epididymis and vas deferens, thus preventing the escape of spermatozoa from the testes. This is by far the most frequent cause of azoöspermism, and in the great majority of cases is due to gonorrhœal epididymitis. It may also be due to tubercular, malignant, or syphilitic disease of these organs. It is held by some good authorities that epididymitis of one side may abolish the function of the opposite gland.

e. To nervous exhaustion or neurasthenia, attended with abnormal seminal and prostatic discharges, and with various degrees of impotence, all of which is usually brought about by onanism, venereal excesses, or ungratified desire. As a result of impaired nutrition induced by perverted innervation, the secretory activity of the testes is interfered with, and either the evolution of the spermatozoa is arrested, or their number and activity are diminished (S. W. Gross).

The diagnosis of azoöspermism must be made by repeated examinations of the ejaculated fluid, if such there be, under the microscope.

The treatment is in many cases evidently *nil.* In advancing atrophy of the testicles, galvanism gives some promise of good. In syphilitic orchitis or epididymitis, prompt and persistent treatment may avert the calamity or restore fertility. In bilateral epididymitis from other causes, early and vigorous antiphlogistic treatment will often prevent occlusion. But even if this exist, it may sometimes be overcome by iodide of potassium, bichloride of mercury, and the local use of mercurial ointment or oleate of mercury.

2. *Aspermatism,* or the failure to ejaculate semen during copulation, may be due to the following causes :

a. Organic lesions preventing the discharge of seminal fluid into the urethra, or preventing its ejaculation through the meatus. Congenital occlusion, absence or deviations of the ejaculatory ducts, have occasionally been met with. Stricture of these ducts and deviation of their orifices, due to inflammation or injury, are more frequent. This may follow gonorrhœa, blows on the perineum, or the operation of lithotomy.

Semen having been delivered in the urethra may fail to be discharged properly, owing to some obstruction anterior to the prostate gland. If this obstacle is in the posterior portion of the canal, the fluid will pass backward into the bladder ; if near its orifice, the semen will flow out after erection has ceased. Stricture of the urethra is the most common of these obstacles. A stricture which permits the flow of urine when the penis is flaccid may prevent the escape of semen during erection. More over, according to Gross (*loc. cit.*) : "In these cases the fault is to be ascribed less to the organic contraction than to the spasm of the muscular walls of the urethra beneath the sensitive mucous membrane, through which the opening is temporarily occluded."

The escape of semen is occasionally prevented by a tight phimosis. Finally, it may be due to induration of the corpora cavernosa, which sometimes results from injuries, and sometimes seems to be associated with the gouty diathesis.

b. Aspermatism may exist in cases where there are no such organic defects or obstacles as are mentioned above, and no external anæsthesia. This is attributed by Rosenthal and others to the "absence of excitability in the lumbar reflex ejaculatory centre."

Such subjects commonly give the general symptoms of neurasthenia and a history of masturbation, sexual excesses, repeated attacks of gonorrhœa, etc. S. W. Gross is of the opinion that in many of them there will be found inflammation and hyperæsthesia of the prostatic urethra, with accompanying lesions, which maintain, and are probably the cause of, the diminished excitability of the lumbar ejaculatory centres. This is important, as indicating possible cure by the use of steel bougies and other appropriate treatment.

c. Anæsthesia, or insensibility, of the glans penis is an occasional, though rare, cause of aspermatism, and a case is reported by Curling, in his work on "Diseases of the Testis," in which he relieved the difficulty by applying the acetum cantharidis to the gland.

d. Mental causes, such as disgust, anxiety, etc., may sometimes interfere with ejaculation, just as they often prevent erection.

Diagnosis.—The fact that semen is not ejaculated during intercourse is apparent to the patient himself, and will probably be the reason of his consulting the physician. The diagnosis as between the various forms, or causal conditions, depends on the history of the case, a careful examination of the genital organs, the question of whether semen escapes with the urine or from the urethra after intercourse, and on the consideration of other points which have been mentioned in the description of the different varieties.

Treatment.—A number of the organic lesions which cause aspermatism are plainly beyond the reach of treatment. In case of phimosis circumcision should be performed ; strictures should be dilated or divided. In the atonic variety, if the insensibility of the lumbar nerve-centres is associated with inflammation and hyperæsthesia of the prostatic urethra, this should be treated by the systematic introduction of the conical steel sound. If granular patches in the urethra fail to yield to this method, astringents, as solutions of nitrate of silver of from ten to thirty grains to the ounce, may be carried to the part by some of the catheter syringes or other applicators in vogue. If, on the contrary, the prostatic urethra is not sensitive and no stricture exist, tonics are indicated, as iron, quinine, strychnine, cold sitz-baths, and perhaps galvanism. In anæsthetic aspermatism the faradic brush to the penis or vesication of its surface, as in Curling's case, may succeed.

3. *Misemission.*—In this form of sterility fertile semen may be secreted and ejaculated, but for some reason it fails to be so deposited in the female organs as to come in contact with the ovum and impregnate it. This is usually due to malformations of the urethra, as hypospadias, epispadias, or fistulous openings in the urethra following injury or stricture. The subjects of these deformities are not always sterile, inasmuch as semen deposited at the mouth of the vagina may find its way into the uterus. Congenital or acquired shortening of the frænum may so displace the meatus as to direct it downward or backward, a fault which may be remedied by division of the frænum. *Edward W. Schauffler.*

STERNUTATORIES, or errhines, are substances which, when applied to the nasal mucous membrane, cause sneezing and increased secretion. Properly speaking, there is a distinction between the two terms, errhine being used to denote an agent which increases the nasal secretions, while a sternutatory causes sneezing only. But as the act of sneezing is almost always accompanied by increased secretion, the distinction between the two classes of remedies is practically without a difference.

In former times sternutatories were much more commonly employed than they are at present, and older writers were wont to lay great stress on the efficacy of these agents in the treatment of many apparently dissimilar conditions. Their use was recommended (1) to restore suspended respiration ; (2) to effect the expulsion of foreign bodies from the air-passages ; (3) to increase the secretion of the nasal mucus or of the tears, or to expel accumulated mucus from the sinuses ; (4) to awaken the action of the encephalon, restore sensibility, or excite uterine action. At the present time, remedies of this class are out of fashion, and the only applications to which they are put are to excite sneezing for the sake of the pleasurable sensations that it causes, to increase the nasal secretions in the dry stage of coryza, and to clear the nasal passages and the adjacent sinuses of accumulated mucus. It is possible, however, if the present tendency of attributing many and diverse morbid conditions to the score of nasal reflexes should prevail, that future generations will restore the sternutatories to their ancient rank among the most prized of therapeutic agents.

The list of substances which have been employed at one time or another for the purposes above enumerated is

as long as the moral law, and embraces nearly every drug which can be reduced to a fine powder, and even many gases, such as ammonia. To enumerate only a few of them, we have rosemary, lavender peppermint, spearmint, white and black hellebore, stavesacre, mustard, euphorbium, betonica, ginger, iris, the peppers, calomel, bismuth, the alkaline carbonates, ipecac, tobacco, sweet marjoram, and a host of others. At present this list is practically restricted to half a dozen substances, the chief of which are tobacco, ipecac, veratrum album, quinine, camphor, and cubebs. Tobacco snuff is seldom employed now, except as a luxury, but the others just mentioned enter, one or all, in varying proportions, into the composition of the different catarrh snuffs prescribed by physicians or sold as proprietary remedies.

The following are some formulæ for catarrh snuffs which may serve a useful purpose in the early, dry stage of a coryza, or later when there is an abundant secretion of tenacious mucus which is dislodged with difficulty: ℞. Quin. sulphatis, gr. xx. (1.3); potassii chloratis, ʒ j. (4.0); amyli, ℥ j. (30.0). M. ℞. Pulv. ipecac., gr. v. (0.3); quin. sulphatis, ʒ ss. (2.0); pulv. camphoris, ℥ ss. (15.0); sacchari albi, ℥ jss. (45.0). M. ℞. Acidi salicylici, gr. x. (0.6); pulv. camphoris, ʒ j. (4.0); pulv. acaciæ, ʒ ij. (8.0); pulv. cubebæ, ℥ ss. (15.0). M. ℞. Morphinæ sulphatis, gr. 2 (0.12); bismuthi subnitratis, ʒ vj. (23.0); pulv. acaciæ, ʒ ij. (8.0). M. This powder, as all others containing morphine, must be used with some caution, ʒ ij.–iij. (8.0–12.0) being as large a quantity as can be safely given to an adult in the twenty-four hours. An errhine which formerly enjoyed much repute was the cephalic snuff—pulvis asari compositus—composed of powdered lavender leaves, one part, sweet marjoram (origanum majorana), one part, and asarum, three parts.

In cases of suspended respiration tickling the interior of the nose with a feather will sometimes cause a deep inspiratory effort, followed by a sneeze, and thus restore the breathing. This is sometimes even more efficacious than cold affusions, slapping the body, and other means commonly employed; for the Schneiderian mucous membrane is among the last of the parts to lose its sensibility in cases of unconsciousness, and will often respond to this stimulus after the integument has become insensible.

Thomas L. Stedman.

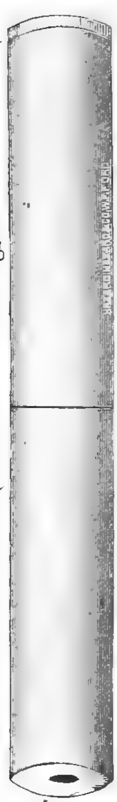

Fig. 3710.—Laënnec's Stethoscope. *a*, Plug; *b*, *c*, sections; *d*, aural extremity.

STETHOSCOPES. Historical Sketch.—The credit of having invented the stethoscope has been variously attributed to Hippocrates, Bayle, Hook, Laënnec, and others. It is certain, however, that Laënnec was the first to make the idea practically useful. He hit upon it accidentally, by using a roll of paper which he was holding in his hand. His first instrument was a cylinder of paper compactly rolled and kept in shape by paste. The stethoscope subsequently adopted was a cylinder of wood an inch and a half in diameter and a foot long, perforated longitudinally by a bore three lines wide, and hollowed out into a funnel shape at one end to the depth of an inch and a half. A plug of wood fitted into this hollowed extremity with a perforation through it of the same diameter as that of the rest of the tube. This was used in auscultating heart sounds. It was discarded in stethoscopes made at a later date. The instrument was made in two sections for convenience of carrying. Piorry introduced a more slender instrument, with ivory cap, and later this was altered and made of wood only. An instrument in which the pectoral end was trumpet-shaped, was devised by Dr. Williams, of London, about 1843. Since then a large number of monaural stethoscopes have been devised, and descriptions of them are to be found scattered through various medical publications. They have been made of metal, wood, hard rubber, papier-maché, and other materials, used either alone or in combination. Most of these stethoscopes are hollow, the bore of the tube being pretty uniform throughout, except at the pectoral extremity, where it is expanded and bell-shaped. Solid wooden stethoscopes have also been devised, but these are more especially useful in conveying percussion sounds when the method of auscultatory percussion is practised. The monaural instruments do not differ from one another in any important particular. A few are combination instruments, having

a percussor and pleximeter attached, or a clinical thermometer, a female catheter, etc., hidden away in them. Among others who have devised monaural stethoscopes may be mentioned Quain, Stokes, Arnold, Barclay, Elliottson, Dobell, Loomis, Burrow, Clark, Cammann, and Ferguson.

M. Landouzy, of Paris, in 1850, constructed a stethoscope with a bell-shaped chest-piece, with a number of flexible tubes attached, by which several observers at once could auscultate. A single tube was designed for each person, but by the use of two tubes it became a binaural instrument. It was necessary to hold the tubes in the ears by the hands, and it was not found to be of much practical use. Many years previously Dr. Williams, of London, had been accustomed to use a binaural stethoscope made of two metal tubes attached to the bell of an ordinary stethoscope, and with flat ear-pieces. This conveyed sound with increased intensity, but was inflexible, clumsy, and awkward of application. The double stethoscope of Dr. Leared, shown in the Great International Exhibition of 1851, was a great improvement. It is made entirely of gutta-percha. The two tubes are attached at one extremity to a bell-shaped chest-piece, and at the other to ear-pieces similar to those of the monaural stethoscope. These tubes being separated and applied to the ears, ex-

Fig. 3716.—Intracostal Solid Cedar Stethoscope.

erted a certain amount of pressure by their own elasticity. To use this instrument ordinarily in practice, however, would require three hands, one for each ear-piece, and another to manage the pectoral end. In 1851 Dr. Marsh, of Cincinnati, patented a double stethoscope. This had a membrane stretching over its objective end, and two gum-elastic tubes leading from the chest-piece to the ears. In this instrument the ear-pieces were inconvenient, and the sounds conveyed were muffled and confused. These circumstances rendered it of little value.

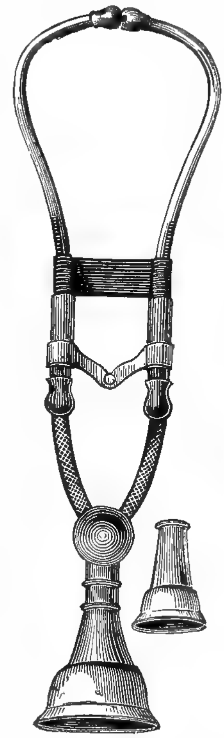

Fig. 3717.—Cammann's Binaural Stethoscope.

Dr. G. P. Cammann devised a binaural stethoscope which, after considerable labor and expense, was perfected in 1852. He was familiar with the instruments of Landouzy and Marsh, and his stethoscope, therefore, was not a new invention, but was, and is now, the best instrument of the kind devised. It is light, durable, easily carried, and a good conductor of sound. The attachment of a rim of soft rubber to the chest-piece, as devised by Dr. Snelling, is of advantage in some cases in applying it more closely to the inequalities of the chest. Oval chest-pieces are also made, which enable the end of the stethoscope to be pressed into the intercostal spaces. In most of the instruments now made the rubber band which served to draw the two tubes together is replaced by a spring. In the latest improvement the spring is placed in the screw which binds the tubes together (Fig. 3721). A considerable variety of flexible stethoscopes are now in use. The credit of having first used one is probably due to Dr. Pennock, of Philadelphia. They may be generally described as consisting of a chest-piece, long flexible rubber tubes, and round ear-pieces. The ear-pieces are held in place either by being firmly pressed into the meatus, or by a spring passing over the head or under the chin. A flexible stethoscope was devised by Mr. Brown, in which the ear-pieces are oval. When placed in the ear, with the long diameter vertical, they are said to remain readily in position. The differential stethoscope of Scott Alison is similar in mechanism to Cammann's, but has two chest-pieces, one for each ear, enabling the sounds from different regions of the chest to be conveyed to the two ears at the same time. The hydrophone is another instrument devised by Alison. It consists of an india-rubber bag, about the size of a large watch, and filled with water. Another inventor had previously constructed a wooden instrument filled with water, but it was not practically useful. Alison found that when water was interposed between two conducting media, sound was conveyed to the ear with increased intensity. The hydrophone may be employed as an instrument by itself, or in aid of the stethoscope.

Fig. 3718.—Scott Alison's Differential Stethoscope.

Dr. McBride has devised for use in auscultatory percussion a solid binaural stethoscope of hard rubber, with chest-piece sufficiently small to fit in the intercostal spaces. Dr. Constantin Paul devised a stethoscope with two flexible tubes leading to the ears, and a hollow chamber in the chest-piece connected with a rubber bulb by a long flexible tube. If the air in the hollow chamber is exhausted the instrument is held firmly against the chest. A modification of the chest-piece of Cammann's binaural stethoscope, which can be screwed on in place of the usual chest-piece, has been devised by the writer. In the pectoral end is an air-chamber, which is completely closed by pressure against the chest. Connected with this chamber by a small tubular opening is a rubber bulb, through which the sound-conducting tube passes. By pressure upon this bulb, when the instrument is held in position, the air is exhausted in the hollow chamber and the stethoscope is held firmly to the chest-wall.

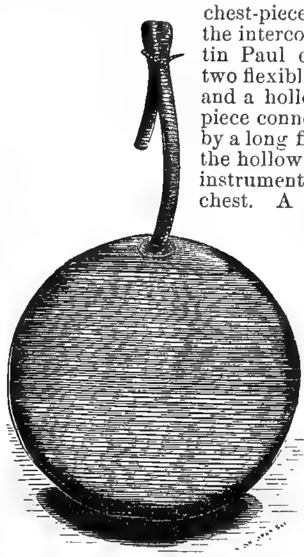

Fig. 3719.—Alison's Hydrophone.

Dr. Heineman, of New York, has devised an attachment to the binaural instrument, in which, by an admirably arranged piece of mechanism, the stethoscope is held firmly against the chest by means of a metal rod extending from the chest-piece to the chin, and both hands are left free.

Dr. D. M. Cammann devised a binaural hydrophone with the two tubes made of hard rubber, and thin hard-rubber caps at the aural extremities. The pectoral extremity is covered by a diaphragm of soft rubber, and the instrument is filled with water by means of a faucet. The chest-piece has been already described as a modification of the ordinary binaural stethoscope, and is held firmly against the chest, leaving both hands free. It is intended for use in practising auscultatory percussion.

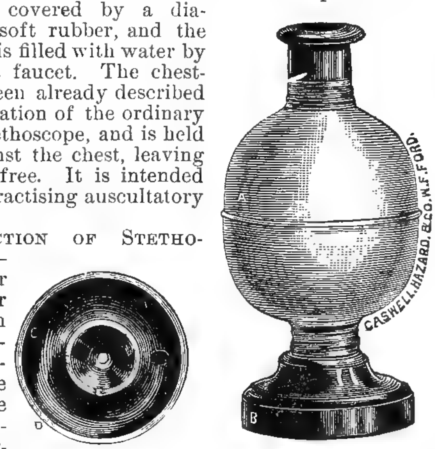

Fig. 3720.—Cammann's Modified Chest-piece. *A*, Rubber bulb; *B*, pectoral end; *C*, air-chamber closed by pressure against the chest; *D*, outer rim; *E*, inner rim.

Construction of Stethoscopes.—The rules for the proper construction of stethoscopes cannot, in the present state of our knowledge, be formulated with scientific exactness; nevertheless, a knowledge of the laws of acoustics and of the results of the experiments of others, will aid us in constructing instruments less faulty th n many of those now in use. In selecting a material, one should be chosen that, as far as possible, is light, durable, and a good conductor of sound. For the monaural stethoscope nothing has been found better than a light, firm, vibrating wood

like cedar. The fibres should run in the direction of the length of the stethoscope. Mahogany, deal, and lime-wood answer well, but the heavier woods, as oak, beech, lignum vitæ, and boxwood, are inferior and deaden the sonorous vibrations of the bodies upon which they are applied. The quality that makes wood desirable is the same that applies in its use in violins, in sounding-boards for churches, and in the walls of concert-rooms. Other materials, although inferior, are good conductors of sound. Ebonite, a preparation of india-rubber, has the advantage of being light and durable, and easily moulded into shape. The metals, horn, papier-maché, gutta-percha, and ivory are good conductors, and have all been used for this purpose. Hollow stethoscopes are most desirable, as some sounds are conducted best through the solid walls, while others are transmitted most perfectly through the enclosed column of air. The latter is the case with the aërial sounds of the chest, the solid wall of the stethoscope acting as a sounding-board, receiving and transmitting the weakest vibrations. In the practice of auscultatory percussion, a solid wooden stethoscope or the binaural hydrophone is most useful, as sounds produced in solids are best conducted through homogeneous media; but even in this case the ordinary hollow instrument will usually be found to convey sound with sufficient intensity for all practical purposes. The bore of the stethoscope and the hollow in the chest end should not be too large, else there will be caused a confused reverberation of sound; nor should the wall of the stethoscope be of great thickness, both on account of superfluous weight and because the weaker vibrations are thereby checked. It is best that the stethoscope should be of one material throughout and in a solid block. This is not essential, however, and in the binaural instrument is not possible. Theoretically the breaking of continuity, by having it in several pieces, would impair the conducting power; but practically the difference is found not to be as great as might be expected. Flexible stethoscopes, in which the tubes are of soft rubber, or of wire covered with some pliable material, are useful in some cases, but the sounds are modified by reverberation, especially when the tubes are long and with large hollows. The length recommended by Laënnec was one foot divided in two for convenience of carrying. This is unnecessarily long, and six inches is now the usual length. The length of the binaural instrument, from ear to chest-piece, varies from ten or twelve to sixteen or seventeen inches. Most of the binaural instruments have two chest-pieces, one small and narrow, the other trumpet-shaped, which can be screwed on at pleasure. The modified chest-piece may also be used, and can be screwed on in the same way. The smaller end can localize sounds best, and is easier of application to the chest; the larger is more useful in examining the chest rapidly. The edges should not be too sharp, but rounded off both toward the circumference and toward the centre. The ear-piece of the monaural stethoscope ought to be large enough to cover the concha and to close the external meatus. It may be flat, but the most convenient form is with a depression between the circumference and the centre, the latter being considerably elevated. The binaural instruments have small circular knobs, which should not be too large nor too small. If too large, they do not fit closely and allow external sounds to enter; if too small, they cause discomfort by pressure. No instrument will suit all ears, and a stethoscope should be fitted to the ear as a shoe is to the foot.

Fig. 3721.—Cammann's Binaural Hydrophone.

Value of the Stethoscope.—In considering the value of the stethoscope it is taken for granted that the instrument used is reliable, and that the auscultator knows how to use it. Some skilful auscultators advocate its continual use; others, equally skilful, advise that it be used only occasionally. The cause of this difference of opinion probably lies partly in difference in the acuteness of hearing and the extent of the training of different observers, and partly is a matter of habit. That the habitual use of the stethoscope does after a time render the sense of hearing less acute to the sounds heard over the chest, in immediate auscultation, is, I think, an undoubted fact. Yet the stethoscope is a valuable instrument, and although it is not always needed, often we cannot attain to a full knowledge of a case without making use both of mediate and immediate auscultation. Often a doubtful or half-heard sound has been clearly brought out and appreciated by the use of the stethoscope; but still oftener, I think, has a sound scarcely suspected with the stethoscope been made evident by the immediate application of the ear. It requires some practice to become accustomed to its use, especially to that of the binaural instrument. In the latter some sounds are exaggerated, while others are impaired, and there are not the distinctness and simplicity that there are when we use the ear or the monaural instrument. It is an acoustic fact that sounds are better heard with two ears than with one, and virtually the double stethoscope enables us to place two ears on the chest at the same time. The modified instrument increases the intensity of sounds both by bringing the pectoral end into the closest possible contact with the chest, and by both the hollow air-chamber and the rubber bulb acting as resonators. It also leaves both hands of the auscultator free. Alison's hydrophone may be used either by itself or placed between the end of the stethoscope and the chest, thereby increasing the contact and the conducting power when it is difficult to bring the inflexible end of the instrument into close apposition with the chest-wall.

The value of the stethoscope for purposes of modesty, cleanliness, and convenience, and for examining the supraclavicular and axillary regions which cannot readily be reached by the ear, are obvious, and need only to be mentioned to be appreciated.

Donald M. Cammann.

STOMACH. The stomach is a dilatation of the intestinal tube, and forms the connection between the œsophagus and the duodenum. In the adult it is a pyriform sac, concave on its upper border (lesser curvature), and convex on its lower (greater curvature). The œsophagus enters its upper part at the distance of about one-fourth or one-fifth of its long diameter from the left extremity (cardiac orifice). The portion to the left of the cardiac orifice is called the fundus. From the cardiac orifice the stomach tapers until it merges into the duodenum. The

outlet of the stomach is marked externally by a constriction (pylorus). A short distance from the pylorus is a narrowing, more marked above than below, which indicates the boundary of the *antrum pyloricum.*

Occasionally a second constriction is found near the middle of the stomach.

The cardia lies behind the sixth and seventh right costo-sternal articulations; the pylorus between the tip of the ensiform cartilage and the edge of the ribs. The lesser curvature lies along the left edge of the vertebral column. The greater curvature, beginning a little to the left of the sixth costo-sternal articulation, rises to the fourth intercostal space, lying at this point above the apex of the heart; thence it goes downward and to the left in a nearly circular direction until it reaches the lower border of the seventh rib, then continues its course to the right until it reaches the middle of the epigastrium, and finally rises to the edge of the floating ribs, on a level with the tip of the ensiform cartilage. The diaphragm rests upon the greater part of the left segment of the stomach. The fundus touches the spleen and left kidney. The pancreas, with only the omentum and splenic artery and vein intervening, rests against the lesser curvature and the body. Behind this again is the great solar plexus of nerves and the cœliac axis. The pyloric end of the stomach is covered by the liver; the greater part of the lower border of the greater curvature rests upon the transverse colon (Fig. 3722).

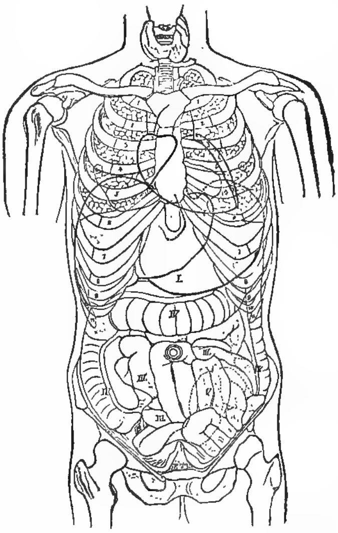

FIG. 3722.—View of the Abdominal Organs from in Front. (From Ranney, after Luschka.) The numerals are placed upon the respective ribs: I., the stomach; II., duodenum; III., ileum; IV., colon; V., sigmoid flexure.

In infancy the stomach is more fusiform in shape, and its direction is more perpendicular, than in adult life.

The position is said to change when the stomach is distended, the greater curvature being carried forward and upward, the anterior surface being raised and the posterior depressed. This change in position has, however, been denied by some.

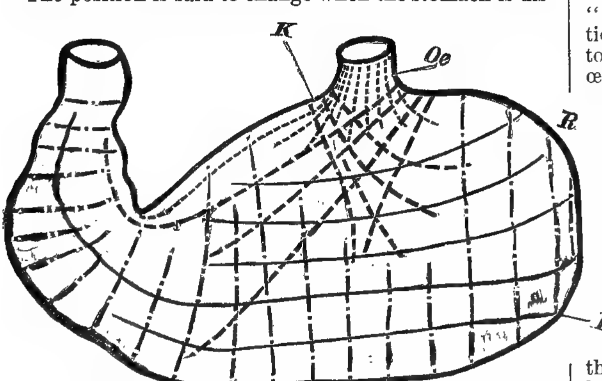

FIG. 3723.—Outline of the Stomach, showing Constriction of Antrum Pyloricum and Direction of Muscular Fibres. R, Circular muscular layer; L, longitudinal muscular layer; Oe, radiation of œsophageal fibres; K, saddle-like bundles.

When full, the stomach is from ten to twelve inches in length, and at the boundary of the fundus, the broadest part, it is from three to four inches in breadth. From this point it diminishes until it is only one inch in diameter at the pylorus. Its capacity is from five to eleven pints (Henle). The thickness of the walls, which increases toward the pylorus, varies according to the degree of muscular tonus, the average being from 2 to 3 mm. ($\frac{1}{12}$ to $\frac{1}{8}$ inch). The weight is about four and a half ounces in the male; it is less in the female.

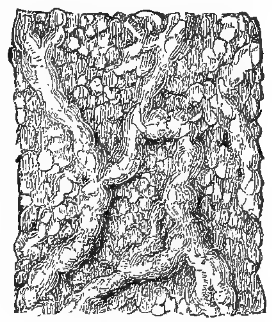

FIG. 3724.—Mammillated Appearance of the Mucous Membrane of the Stomach. (Henle.)

It is composed of four layers: serous, muscular, submucous, and mucous.

The *serous, outer, layer* was derived originally from the peritoneum. A double layer passes from the liver to the lesser curvature of the stomach (the gastro-hepatic or lesser omentum). At the stomach it splits, and one layer passes in front and the other behind. At the greater curvature these layers unite again, to form the great omentum. To the left of the cardia, a fold similar to the lesser omentum passes between the diaphragm and stomach (the gastro-phrenic ligament).

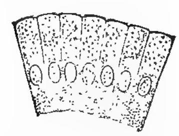

FIG. 3725.—Epithelium of the Mucous Membrane of the Stomach; fresh. (Heidenhain.)

The *muscular coat,* of smooth muscular fibre, consists of three layers—longitudinal, circular, and oblique.

The longitudinal fibres are in direct continuity with those of the œsophagus. Some of the œsophageal fibres are lost at the cardia; of the remainder a thick layer passes along the lesser curvature to the pylorus, another bundle of fibres passes along the greater curvature, and others radiate from the cardia. Two "saddle-like collections of fibres," one to the right of the œsophagus and radiating to the left, the other to the left of the œsophagus, radiating to the right, form a sort of sphincter around the orifice; the latter bundle, the thicker, reaching as far as the *antrum pyloricum.*

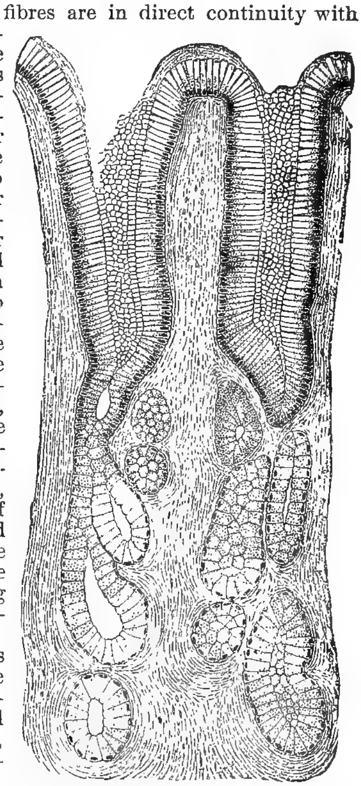

FIG. 3726.—Glands of the Stomach. From the neighborhood of the pylorus. (Ebstein.)

The circular is the most complete layer. At the pylorus it is thickened into a sharp ring, which forms the pyloric sphincter.

The inner, oblique, layer is the continuation of the inner circular fibres of the œsophagus. It spreads over the interior of the stomach to the left of the cardia, in a direction to form an oblique angle with

the axis, to the pylorus, and gradually loses itself on the two sides (Fig. 3723).

The submucous layer is composed of loose connective tissue, and serves as a bed for the net-work of blood-ves-

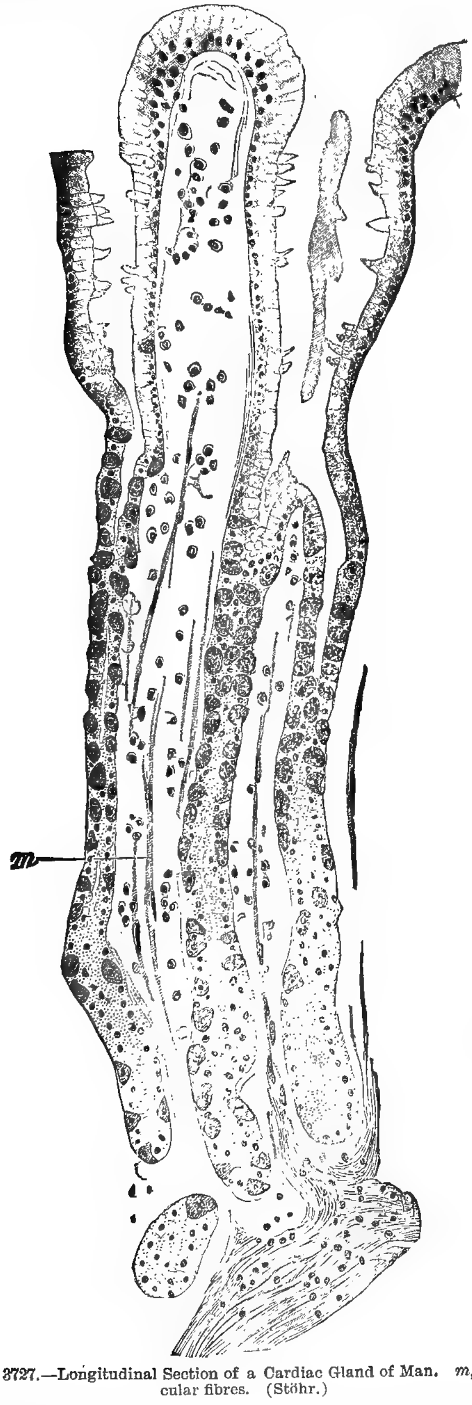

Fig. 3727.—Longitudinal Section of a Cardiac Gland of Man. *m*, Muscular fibres. (Stöhr.)

sels and lymphatics which supply the mucous membrane.

The *mucous membrane* is soft and pulpy, and is in marked contrast with the shining membrane of the œsophagus, from which it is separated at the cardia by a sharp zigzag line.

The color varies with the age of the individual. In the infant it is pink, but becomes reddish-gray and gray as age advances.

When the stomach is empty the contraction of the *muscularis mucosæ* throws the mucous membrane into folds (*rugæ*) which lie, for the most part, in a longitudinal direction. The rugæ are obliterated when the stomach is distended.

Between the rugæ run minute furrows, which divide the surface into rounded eminences flattened at the top (mammillations); they are from two to three mm. ($\frac{1}{12}$ to $\frac{1}{8}$ inch) in diameter (Fig. 3724).

Besides the mammillations there are also elevations caused by the presence of the agminated glands.

The stomach is very vascular. The *arteries* are derived from the cœliac axis, branches passing to each end of both the upper and lower curvatures. Here they penetrate beneath the peritoneum and anastomose, to form two vessels which run the length of the curvatures, one above and the other below. These vessels divide the organ into equal halves.

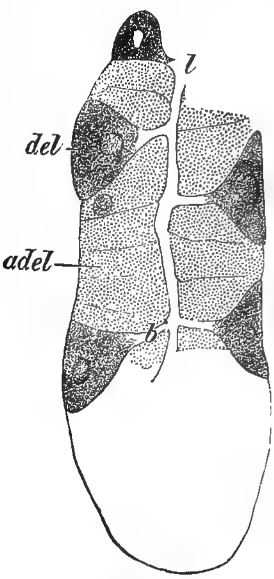

Fig. 3728.

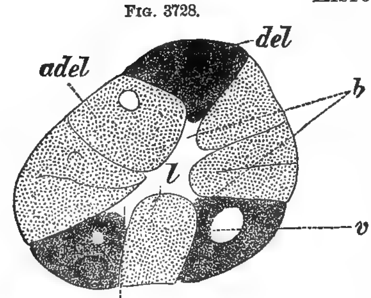

Fig. 3729.

Figs. 3728 and 3729.—Longitudinal and Transverse Sections of a Gland from the Fundus of the Human Stomach. The transverse section is made near the base of the gland. *l*, Lumen; *v*, vacuole; *del*, delomorphous, and *adel*, adelomorphous parietal glands; *b*, prolongations of the delomorphous cells. (Stöhr.) × 600.

The *veins* accompany the arteries and have essentially the same course, but they are of larger calibre, fewer in number, and less complex.

The *lymphatics* also follow the course of the blood-vessels, to form a plexus in the submucous connective tissue from which the lymphatic capillaries arise.

Lymphatic glands are found in the course of the lymphatic vessels along the two curvatures.

Histology. — *The serous layer* is 0.03 mm. in thickness, and resembles the peritoneum in microscopic character.

The muscular layer is composed of smooth muscular fibre.

The submucous layer is composed of loose connective tissue, with a few fat-cells.

The mucous membrane, however, is the layer of special interest, both histologically and physiologically. A perpendicular section shows the membrane to consist of an epithelial layer separated by a basement membrane from a muscular layer (*muscularis mucosæ*).

The *epithelium* is of the columnar variety, and presents a sharp contrast to the flat epithelium of the œsophagus. The cells are long and slender, and are filled with granules. They contain near their centre a large, oval nucleus. "Goblet-cells" are sometimes found. Scattered among these are rounded cells, sometimes in nests (Fig. 3725).

The surface epithelium dips down at short intervals to form the mouths of the gastric glands. These glands begin at the cardia and extend to the pylorus. They lie so thickly together that, in a transverse section, the mucous membrane appears striated, and seems to be wholly

Stomach.

composed of them. They extend through the membrane and rest upon the muscular layer beneath. The glands, at first sight apparently all alike, are, upon closer examination, found to be of two classes: those found near the pylorus (pyloric glands), and those found near the cardia (cardiac glands).

The *cardiac glands*, formerly called peptic glands, are longer and more complicated than the pyloric. They consist of a cylindrical tube, which gives off at its lower extremity three or four branches.

The upper and broader tube is lined by cells which resemble the cells of the mucous membrane, except that they are perhaps a trifle smaller. Lower down in the tube the cells become shorter and slightly broader, and at the point where the branches are given off they are, in a longitudinal section, nearly square (cubical cells). From this point they broaden, and toward the bottom of the gland become irregular in outline. Lying next the basement membrane, and covered by the irregular cells, is a fourth variety of cell—the parietal cell — sometimes called peptic cell. These cells are ovoid in shape and much darker than the others. When swollen they nearly touch one another. Two to four are usually seen in a section of the gland parallel to the surface of the stomach. The net-work described by some observers in these cells has not been demonstrated.

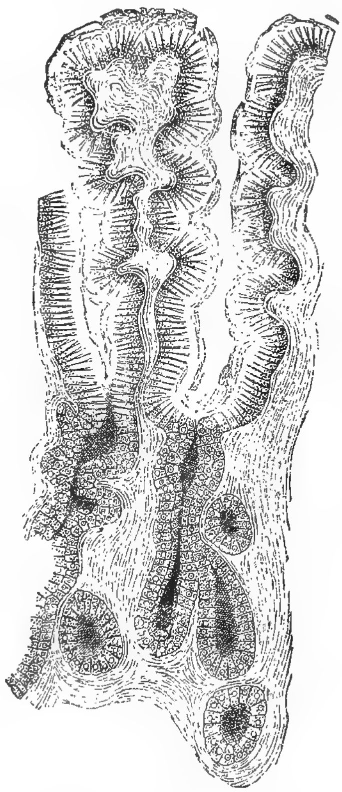

FIG. 3730.—Glands of the Stomach, from the Neighborhood of the Pylorus, showing the Changes occurring during Digestion. (Ebstein.)

The *pyloric glands* resemble the cardiac glands in general appearance, but their upper portion is broader, and the branches at the bottom are shorter and fewer in number. They contain only the first and second varieties of cells. The two kinds of glands shade gradually one into the other.

The number of glands in a square millimetre ($\frac{1}{25}$ inch) is about one hundred. In the whole stomach there are about forty-nine thousand (Henle) (Figs. 3726, 3727, 3728, 3729). The depth of the first part of the glands "in the normal stomach is, at the cardia, about 0.2 mm. (.0079 inch), but toward the pylorus it increases in a marked degree. The transverse diameter, including the epithelium, is about 0.07 to 0.10 mm. (.0028 to .004 inch), of which about 0.05 mm. (.002 inch) is included in the height of the epithelium. The height of the epithelium is 0.025 mm. (0.001 inch). The passages average 0.02 mm. (0.008 inch) in breadth; exceptionally they are 0.06 mm. (.024 inch)" (Henle).

The basement membrane bounds the epithelium of the stomach and its glands. It is a membrane composed of flattened cells, which send out prolongations among the epithelial cells of the mucosa and of the glands.

The muscularis mucosæ is better developed in many of the lower animals than in man. It consists of two layers of smooth muscular fibre, an outer circular, and an inner longitudinal, layer. From the inner layer prolongations are sent up among the glands.

A use for these prolongations in emptying the glands of secretion during digestion can be imagined.

The mucous membrane and glands present different appearances at different times. The cells of the mucous membrane in the intervals of digestion are slightly larger at the top than at the bottom, and are filled with a clear, muco-albuminous substance (mucigin, Schäfer) in which the granules are suspended. Consequently the tops of the cells appear more transparent and less granular than the bottom. During digestion the mucigin is discharged, carrying with it a considerable number of granules. After digestion, therefore, the cells become shorter and more opaque. During digestion the glands of both kinds discharge granules. The parietal cells of the cardiac glands at this time swell to nearly double their size; they resume their original appearance after digestion is completed (Fig. 3730).

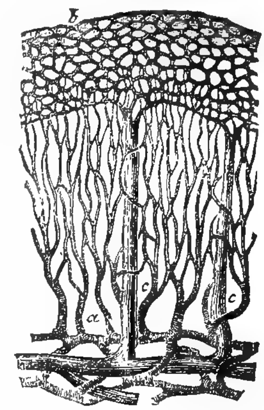

FIG. 3731.—Plan of Blood-vessels of the Stomach. *a*, Arteries; *b*, rings around the mouths of the glands; *c*, veins. (Quain.)

At the pyloric orifice is a ring of *racemose glands* which resemble the duodenal glands.

Papillæ also begin to appear in the neighborhood of the pylorus, which are the beginnings of the papillæ of the small intestine and resemble them in structure. "These *plicæ villosæ* are about 0.05 mm. in height" (Henle). They are sometimes absent.

The *blood-vessels* of the stomach are arranged in a manner which differs from that in any other organ, except the colon. The arteries form a net-work in the submucous connective tissue. From this net-work large capillaries or arterioles arise, which pass upward between the glands, giving off in their course two or more branches which connect with the other upright arterioles, and form a mesh-work around each gland. At the upper part of the glands they empty into veins, which form rings around the mouths of the glands. They are of considerably larger diameter than the capillaries. They are con-

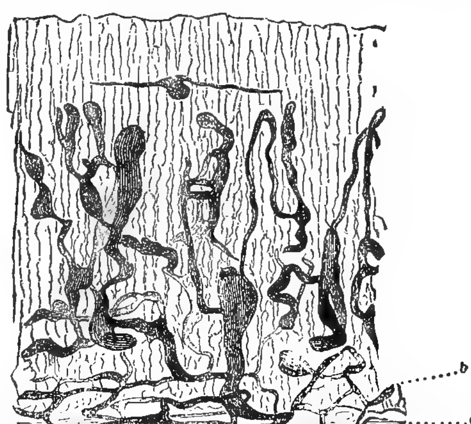

FIG. 3732.—Lymphatics from Human Gastric Mucous Membrane; injected. The tubules are faintly indicated. *a*, Muscularis mucosæ; *b*, plexus of fine vessels at base of the glands; *c*, plexus of larger valved lymphatics in submucosa. (Lovén.)

nected together in a network which empties into a large vein perpendicular to the surface.

In the submucous tissue, these veins empty into another venous plexus which conveys the blood away from the organ (Fig. 3731).

The *lymphatics* are also peculiar. A lymphatic plexus in the submucous connective tissue sends up branches which, as is usual with lymphatics, are very irregular in size and length. In the main they run upward, inosculate with other branches, and end apparently in a blind tube (Fig. 3732).

Lymphatic structures resembling the so-called solitary glands of the small intestine are found scattered throughout the stomach. These are less perfectly separated from the other structures than are the solitary glands. They consist of a reticular structure filled with lymphoid cells. Toward the periphery the reticulum becomes coarser, the cells are fewer, and finally disappear without any line of demarcation. These structures are most abundant in childhood, after which they become fewer, and finally disappear after middle life.

The nerves form gangliated plexuses similar to those of the small intestine. In the muscular layer is a plexus similar to Auerbach's plexus. In the submucous layer is one similar to Meissner's plexus. The termination of the nerves is unknown. *Lester Curtis.*

STOMACH, ORGANIC DISEASES OF THE. Gastritis.—Although there is no distinct dividing line, as regards morbid anatomical changes, between subacute and acute inflammation of the stomach, it is necessary to distinguish clinically between these two grades of gastric disease, because they differ essentially, in symptomatology, in prognosis, and in treatment; while typical cases also present decided points of diversity in their respective pathological anatomical conditions. The writer, therefore, proposes to describe under their combined titles, first, the milder, and then the graver types of gastritis, believing that their juxtaposition will render more apparent both their resemblances and their points of dissimilarity.

I. Subacute and Acute Gastritis. *Etiology.*—The causes of these diseases are predisposing and exciting.

(a) *Predisposing Causes.*—The predisposing, or indirect causes are so similar for both subacute and acute gastritis that a separate enumeration for each disease seems unnecessary, while the exciting, or direct causes differ rather in degree than in kind. The predisposing causes are all conditions, whether general or local, which temporarily impair the vitality of the gastric tissues, thus reducing their power of resisting irritation, and their capacity for the performance of their respective functions. The constitutional conditions favoring subacute and acute gastritis are, thus, transient anæmia and asthenia from whatever source. We accordingly see a predisposition to these diseases in febrile affections, such as typhoid and typhus fevers, diphtheria, the eruptive and malarial fevers, acute rheumatism and gout; while in those persons who are naturally weak, even slighter ailments, such as bronchitis, pharyngitis, or influenza may predispose to these diseases. The predisposing influence of these febrile conditions is readily accounted for by the accompanying diminution in the secretion of saliva and gastric juice, and by the consequent retardation and perversion of digestion. If, in these febrile states, food be administered in such quantity or be of such a quality as to overtax the digestive powers of the stomach, fermentation will ensue and lead to the production of irritating acids and gases. Besides exerting a harmful chemical action upon the gastric mucous membrane, the gases over-distend the organ, thus still further enfeebling its muscles, the contractile power of which has already been impaired by pre-existing systemic weakness. The decomposing mass thus remains, for an indefinite period, in contact with the mucous membrane, constituting one of the exciting causes of gastritis to be presently enumerated.

The use of certain drugs, in disease or in health, may strongly predispose to gastritis, by diminishing the secretion of the digestive fluids and by retarding the peristole of the stomach. Among these medicines may be mentioned opium and its derivatives, belladonna, stramonium, hyoscyamus and cocaine. Chloral, the bromides and other spinal depressants probably exert a similar influence. Local diseased conditions of the stomach and of other organs likewise favor the development of gastritis. To this class of causes belong gastrectasia, whether obstructive or atonic, ulcer, new-growths in the stomach and congestion. Venous congestion of the stomach is produced by obstruction to the portal circulation from many causes, among which the most obvious are weakened heart action, pulmonary and pleuritic diseases obstructing the pulmonary circulation and hepatic diseases preventing the normal discharge of blood from the portal vein. Repeated attacks of gastritis predispose to relapses of the disease by their deleterious influence upon the vitality of the mucous membrane and, perhaps, by impairing the tone of the gastric vessels.

Children are more susceptible than adults to the action of comparatively feeble gastric irritants, because of the inherent sensitiveness of their mucous membranes. Old people, convalescents, and anæmic patients are likewise particularly predisposed, because of their low vitality and of the consequent slight resisting power of their tissues. Asthenia and anæmia from chronic diseases, on account of their more lasting influence, rather predispose to chronic than to subacute and acute gastritis. These chronic diseases will, accordingly, be mentioned under the etiology of chronic gastritis. It is, however, to be remembered that these disorders may, in their inception, lead to transient attacks of subacute and of acute gastritis, which diseases may also be invited by the imposition of unusual digestive tasks upon a stomach ordinarily accustomed to a simple and restricted diet.

(b) *Exciting Causes.*—The exciting causes of subacute and acute gastritis are thermal, mechanical, or chemical irritants. To the first class belong ice-cold, as well as overheated fluids and solids. Mechanical irritation of the stomach may be produced by abdominal contusions, the careless or frequent introduction of hard-rubber stomach-tubes, and the ingestion of sharp, rough, or indigestible solids, or of coarse, uncooked, or superfluous foods. Among the most important chemical irritants are the gases and acids resulting from putrefactive and other fermentative processes in the stomach, too highly seasoned and too acid foods, undiluted alcoholic beverages, as spirits and cordials, drastic cathartics, other irritating drugs, urea and carbonate of ammonia eliminated by the stomach in Bright's disease, and various corrosive poisons, as mercury, arsenic, zinc, nitric acid, sulphuric acid and oxalic acid. Alcohol and the corrosive poisons are chiefly responsible for the most severe cases of acute gastritis, but any of the above-named irritants may act as efficient exciting causes of the disease in an organ already predisposed to inflammation. Most authors mention exposure to cold as a possible exciting cause of gastritis, but regard its etiological influence as problematical. Violent physical exercises, powerful intellectual efforts, or strong emotions, may act as exciting causes of subacute gastritis by arresting digestion, and thus favoring fermentation. In these cases the arrest of secretion may be the effect either of nervous inhibition, or of diversion of blood into other channels, or of both these conditions combined.

Morbid Anatomy.—Opportunities for the *post-mortem* observation of the pathological anatomical changes in subacute gastritis are rare, because the disease tends, almost invariably, to recovery, and such examinations, when obtained, are necessarily misleading because vascular contractions, occurring after death, may quite obliterate the traces of the inflammatory process. On the other hand, *post-mortem* injection and softening of the mucous membrane, or auto-digestion of the gastric walls, may confuse the pathologist. The recorded cases of subacute and acute gastritis in which *intra-vitam* observations have been made upon men and animals, therefore, possess a peculiar importance, and the classical case of Alexis St. Martin, minutely studied by Beaumont, is regarded as the most valuable and reliable source of information in regard to this subject. The gastric mucous

membrane of St. Martin, when moderately inflamed by alcohol or other irritants, presented, according to Beaumont, a mottled appearance, pale areas intervening between small and irregularly shaped spots of a red or bluish-red color. Other spots, white, apparently elevated above the surrounding membrane and resembling patches of false membrane, were sometimes present. The gastric juice was notably diminished in quantity, while the mucus was increased; and when the inflammation was more severe, pus was also abundantly produced. Small venous hæmorrhages occasionally took place from the congested areas, and ecchymoses were also observed.

In *acute gastritis* autopsies are more frequently made and the pathological conditions are consequently better understood than in subacute gastritis. In these cases the mucous membrane, particularly that of the pyloric region, is more opaque than in health, and may present alternating red and pale areas. Sometimes, however, the whole surface is pale, and again, it may be uniformly congested. The membrane is softened, thickened, sometimes ecchymotic, often ulcerated and covered with thick, adhesive mucus or muco-pus, which is sometimes stained with blood, and contains desquamated cylindrical epithelial cells. The ecchymoses and ulcerations are most frequently seen at the apices of the folds in the mucous membrane. The submucous tissues are sometimes swollen and either red or pale. The microscope shows the capillaries of the reddened areas in the mucous membrane to be distended with blood, and this is especially true of the vessels in close proximity to the orifices of the gastric tubules. The ecchymoses present the usual microscopic appearances. The base of the ulcers is sometimes composed of extravasated blood, and sometimes of the submucous tissues. Ecchymoses are also found between the tubules, besides serum, either limpid or blood-stained, and pus. The submucous tissues may be infiltrated with serum and pus. The gastric solitary follicles are, when present, occasionally hypertrophied, and sometimes numerically increased. The lining cells of the mucous membrane are swollen and their desquamation is probably abnormally increased. Great interest centres about the pathological changes in the secreting cells of the gastric tubules. These may remain normal, but they often undergo parenchymatous, and subsequently fatty, degeneration, being thickened, in these respective conditions, by abundant albuminous or fatty granules, and presenting a whitish, opaque appearance. The tubules are sometimes partly filled by cells of this description, and sometimes with amorphous and granular matter. In the most *acute forms of gastritis*, such as are produced by corrosive poisons, false membranes may be developed in the mucous membrane, and sloughing of this membrane and of the deeper tissues may ensue, leading to perforation of the stomach. Many of the above-mentioned morbid anatomical changes are often simultaneously found in the stomach and the duodenum, the disease being then known as gastro-enteritis.

Clinical History. (*a*) *Constitutional Symptoms.*—Subacute gastritis presents the familiar train of symptoms collectively known as acute indigestion, by French authors as *embarras gastrique*, and in popular parlance as a "bilious attack." The symptoms naturally vary within wide limits, in accordance with the severity of the inflammation. The following description aims at reproducing the clinical picture presented by a case of medium severity. In such a case there is loss of appetite, generally repugnance to food, often nausea, sometimes emesis, and occasionally a longing for highly seasoned foods and for condiments or spices. The vomited matter contains the offending material which caused the attack, unless this has already passed into the intestine, mucus, sometimes bile and, more rarely, a little blood. The bowels are generally constipated, but sometimes are relaxed. If diarrhœa is present, enteritis probably exists. Eructations and flatulence are common. The urine is scanty, high-colored, charged with urates, and sometimes contains oxalate of lime, leucine, and tyrosine. Headache is a frequent, but not a constant, symptom; occasionally it is very intense and may then be due to auto-infection with septic materials resulting from fermentation in the stomach. In this connection it is interesting to recall the cases reported by Litten, in which he observed, besides headache, nervous restlessness, great muscular weakness, and finally, marked somnolency. In these cases the expired air had a decidedly fruity odor and the urine showed the reaction now usually referred to the presence of diacetic acid, viz., a bright red-color upon the addition of a solution of the chloride of iron. In some cases the eructations have the odor of sulphuretted hydrogen, but often they are odorless. The mental energy is impaired, the spirits are depressed, and there is ordinarily a sense of physical fatigue or of prostration out of all proportion to the real loss of power. There may also be vertigo and partial aphasia, *tinnitus aurium*, faintness and dyspnœa. The pulse is generally quickened and the temperature raised, but not commonly above 100° or 100½° F. Exacerbations of fever may occur toward evening and after the ingestion of food. In milder cases there is sometimes no febrile movement, the pulse remaining infrequent and feeble, and the surface cold. Chilly sensations and even chills may occur.

(b) *Local Symptoms.*—The mouth is dry, the breath foul, the tongue coated at first, and, later, sometimes red or glazed. There is epigastric tenderness and prominence, generally accompanied with a constant dull pain and a sensation of tension in the stomach. This feeling of repletion is sometimes relieved by emesis or by eructations. The above-named sensations are all intensified by the introduction of food, unless it be cool and liquid. The gastric muscles being relaxed or paretic from overstretching, the food remains undigested in the stomach for a long time, unless removed by vomiting or catheterization. Intermittent, acute pains, resembling those of intestinal colic, often occur, while pyrosis and gastric tympanites are not uncommon. Patients frequently complain of a bitter taste in the mouth. Slight icterus sometimes appears, as a sign of gastro-duodenitis. Labial herpes and urticaria are occasional symptoms. Mild cases of subacute gastritis are usually of only a few days' duration. In more severe cases the inflammation may persist for one, two, or even three weeks. If the disease be still more protracted, it is regarded as constituting chronic gastritis (*quod vide*). When subacute gastritis develops in conjunction with gastric dilatation, the symptoms are more likely to be severe and protracted than in subacute inflammation of a previously healthy stomach. The contents of the stomach are retained for a greater length of time, and fermentation ensues with greater rapidity. The cerebral symptoms are correspondingly intensified, whether from reflex irritation or from auto-infection by means of ptomaïnes. Gastric tympanites and epigastric tenderness are apt to be more marked than in healthy stomachs, but paroxysmal pain is less frequent on account of the flaccidity of the dilated organ. Obstinate constipation is the rule, because the gastric contents pass through the pylorus in very small quantities and their fluid parts are completely absorbed in the small intestine. Prostration is sometimes extreme in these cases. In young children subacute gastritis causes more intense febrile movement, more marked depression, and more serious symptoms, in general, than in adults. It is difficult to elicit exact information from the little patients regarding their subjective symptoms, but the objective phenomena and physical signs are essentially the same as in grown people. Entero-colitis is likely to associate itself with the gastritis in young children, particularly in hot weather, thus constituting the disease popularly known as "cholera infantum," for a description of which the reader is referred to the article in this HANDBOOK treating of that subject.

In *acute gastritis*—which term is here applied to that serious form of gastric inflammation ordinarily caused by immoderate indulgence in alcoholic drinks, or by the action of corrosive poisons—the symptoms and signs are striking, characteristic, and, in serious cases, truly appalling. The first symptom, in cases of great severity, is generally intense burning epigastric pain, accompanied by great tenderness on pressure, and by rigidity of the

abdominal walls. Even the respiratory diaphragmatic movements augment this pain. If the attack is occasioned by caustic substances, there is also pain and burning in the mouth, pharynx, and œsophagus, dysphagia and sometimes aphonia. Nausea, with violent and very painful acts of emesis, soon follows, the matter rejected from the stomach containing portions of the poisonous material, saliva, and often either liquid or grumous blood. The stomach is so irritable that any substance, no matter how bland or how small in volume, is instantly rejected. Even cool water, in teaspoonful doses, is not retained. The thirst is intense and the bowels are constipated, unless some violent irritant has entered the intestine, when there may be active and painful purging. The urine is almost or quite suppressed. There is often violent headache, but the intellect is unimpaired. The face is haggard and expresses fright or apprehension. In the advanced stages of fatal cases the eyes are sunken, the features pinched, and the color ashen. The pulse is frequent and compressible. The temperature is at first elevated, sometimes to a point between 102° and 103° F., but is, later, depressed. The respirations are frequent, superficial and irregular. The surface is at first hot and dry, and later is cold. Sometimes there is icterus from involvement of the duodenum. In cases ending in recovery, gradual amelioration of all these symptoms occurs. In fatal cases asthenia ensues, ending in collapse, which quickly closes the scene. If perforation of the stomach occurs, fatal shock follows, or, if the patient survive the shock, peritonitis causes a lethal issue.

Differential Diagnosis.—The diagnosis is generally easily made. Remittent or typhoid fever of slight severity may be mistaken for subacute gastritis, but the reverse error is more likely to occur, particularly in the case of children. Gastritis is often produced by any febrile disease which arrests the secretions and invites fermentation. Under these circumstances, care must be exercised lest one or the other ailment be overlooked. An examination of the spleen and of the blood, and the use of the thermometer, may decide the question by revealing the absence or presence of conditions characteristic of malarial or of typhoid fever. Leube considers the presence of herpetic vesicles as quite characteristic of gastritis.

Chronic meningitis may simulate subacute gastritis, especially in young subjects, being attended with frequent vomiting, which is, however, explosive and not accompanied by nausea, or by epigastric tenderness. There is, moreover, obstinate constipation in meningitis, while gastritis in children is usually complicated by enteritis, which causes diarrhœa. In the early stages of meningitis the pulse is rather diminished in frequency than accelerated, while the reverse obtains in gastritis. In meningitis there are jactitation and intolerance of light and sounds.

Prognosis.—Subacute gastritis almost invariably ends in recovery, or at most, in badly managed cases, may terminate in chronic gastritis. Acute gastritis, from corrosive poisons, is commonly fatal from collapse or shock. Alcohol in excessive quantities often produces the same result, particularly in cases attended with asthenia from repeated debauches.

Various complications of acute gastritis may contribute to the fatal issue. Chief among these are peritonitis from gastric perforation: the effect on the nervous system, independent of their local action, of some corrosive poisons, like arsenic; œdema glottidis, and enteritis. As sequelæ, may be mentioned gastrectasia, from fibroid constriction following ulceration of the pyloric orifice, and œsophageal obstruction from the same cause.

Treatment.—The indications for treatment, in subacute gastritis, are to remove irritating substances from the stomach and to prevent the ingestion of such articles; to allay the irritation of the mucous membrane, and to temporarily procure for the organ partial or complete relief from the performance of its functions. The measures adapted to meet these indications will vary with the severity of the gastric inflammation. In the mildest cases, nothing is required beyond a reduction of the diet to the minimum quantity consistent with adequate support of the patient, and the exclusion of all irritating foods. Peptonised milk, or milk and Vichy water, in equal parts, with toast or toasted crackers, may be given, in six- or eight-ounce doses, at intervals of three hours. The writer is in the habit of prescribing a powder containing from three to eight grains of sodium bicarbonate and from ten to thirty grains of bismuth subcarbonate, before each drink of milk and Vichy water, or of peptonised milk. The former ingredient is intended to neutralize abnormal acids which may have been formed in the stomach as the result of fermentations, and the latter to soothe the irritated mucous membrane. If there be physical evidences of prolonged retention of food in the stomach, an unirritating laxative, as Hunyadi Janos water, citrate of magnesia, or a seidlitz powder, may be administered at the outset. If there be jaundice, a few grains of calomel may be given and followed, in a few hours, by the saline laxative. In subacute gastritis complicating gastrectasia, the writer has had good results from the gentle use of the soft syphon-tube, according to the method described in the section which treats of Gastrectasia. By lavage, irritating matters are at once withdrawn, and the proper dietetic measures are, subsequently, doubly efficacious. Daily laxative enemata are also to be recommended, besides demulcent drinks, in small quantities, between the doses of milk.

In more acute gastritis, attended by considerable vomiting and febrile disturbance, the ingestion of aliment is to be still farther restricted, or even suspended, for a few hours or days. In these cases nature has generally fulfilled the first indication for treatment, viz., the removal of irritating substances, as is proven by the rejection of simple mucus or of bile, occasionally mingled with blood. Here no evacuant is necessary, and neither emetics nor the syphon-tube are permissible. In acute gastritis complicating atonic gastrectasia, however, the tube may still be employed, as the dilated stomach can be quickly relieved of its irritating contents by this means alone, and enteritis from decomposed foods is, also, thus avoided. The first duty of the physician, in these cases, is to allay gastric irritability, which may generally be effected by placing the patient in bed, withholding all food and drink, applying a sinapism or blister to the epigastrium, and by administering morphia, in doses of one-eighth or one-fourth grain, either dry upon the tongue, or dissolved in a teaspoonful of water. If this be rejected, the vomiting may be controlled by a moderate dose of morphia, given hypodermatically or by the rectum. In all but the most severe cases, small bits of ice, given every few minutes, are very grateful to the patient, mitigating his thirst and cooling the inflamed stomach. Sponging the surface of the body with tepid water also allays thirst and fever. If, however, even the ice-water be not retained, urgent thirst may be relieved by rectal injections of lukewarm water, preceded by a laxative enema. Laudanum, given in the water by rectum, obtunds the sensibility of that viscus, thus favoring the retention of the water, and also controls the gastric tenesmus, the pain, and the emesis. This method of administering the opiate is to be strongly recommended whenever the hypodermatic use of an opiate is objectionable. When the vomiting has been so far controlled that cracked ice is tolerated and may be relied upon to assuage the thirst, or before this time, if the patient be in urgent need of nourishment and support, nutritive enemata may be given instead of those composed of pure water, or of water and opium. It is under these circumstances that rectal alimentation renders its most striking and signal services. The enemata are not to exceed five ounces in quantity, and are to be given every four or six hours. Peptonised milk is, in the writer's opinion, the aliment best adapted for administration by the rectum, as it is practically digested and need only be absorbed by the bowel. Leube's meat solution, as modified by Rosenthal, and defibrinated blood, and Rudische's beef peptonoids, are also of great value. Even sweet milk, to which the white of an egg has been added, given with pepsin and pancreatic extract, is of undoubted service. A few drops of laudanum, added to each enema, prevent the development of rectal tenesmus

and exert a desirable tranquillizing influence. Alcohol may be added, if necessary, for purposes of support, and is particularly useful in asthenic cases of alcoholic gastritis. Laxative enemata are required, once or twice a day, to clear the bowel of undigested matters. When the stomach will tolerate food, the peptonised milk, or the milk and Vichy water, are to be given in small quantities, tentatively, next the carbo-hydrates and fats, and finally, after some days, the solid proteids.

The treatment of toxic gastritis, due to corrosive poisons, has been considered under the heading Poisons, Corrosive, and claims only a passing notice in this place. The first therapeutic measure indicated in these cases, is the prompt administration of such antidotes as are indicated, and, next, the expulsion from the stomach of the poisons. The poisons may be best removed by the soft stomach-tube, to which the stomach-pump may be attached in case of necessity. After the withdrawal of the toxic substances, appropriate emollients and sedatives are in order. The subsequent treatment is identical with that of ordinary acute gastritis. During convalescence from subacute or acute gastritis, great care should be taken to adapt the foods to the capacity of the enfeebled stomach, lest chronic gastritis or atonic gastrectasia be developed. The early use of tonics and of stimulants is contra-indicated on account of their irritating action. The appetite will generally be restored by nature, *pari passu* with the ability to digest substantial nourishment, but a feeble digestion may well be assisted by five grains of pepsin, and fifteen or twenty drops of dilute hydrochloric acid, given in water, an hour after each meal.

II. Chronic Gastritis. *Etiology.*—Most cases of chronic gastritis have their origin in antecedent subacute or acute gastritis, their causes being essentially the same as those of the latter forms of gastric disease. Some of the etiological agents of gastritis are, however, more prone than others to occasion chronic gastritis, because their influence is more protracted. This is true of all chronic, wasting diseases, and of all sources of chronic malnutrition which, by occasioning anæmia, gastric atony and, probably, degeneration of the gastric vessels, interfere with the normal secretion of the gastric juice, enfeeble the muscular coats of the stomach, and thus invite inflammation. In this category belong phthisis, cancer, gout, chronic nephritis, syphilis, rheumatism, chronic malarial disease, neurasthenia, rigid dieting, long fasting and old age. All causes of protracted obstruction to the portal circulation tend to produce chronic gastritis, by maintaining a venous congestion of the stomach. This group of causes, in which all diseases obstructing the pulmonary circulation are prominent members, has been sufficiently considered under the etiology of subacute and acute gastritis. Men suffer more frequently than women from chronic gastritis. Fenwick and Strümpell believe in the existence of a hereditary tendency to chronic gastritis. Among the exciting causes of chronic gastritis are to be particularly emphasized repeated over-indulgence in foods, whether digestible or comparatively indigestible, the habitual use of over-stimulating aliments, imperfect mastication, and alcoholic excesses, or even the use of moderate quantities of alcohol when the stomach is empty. Even perfectly simple food, in proper quantities, may cause chronic gastritis in an enfeebled stomach, or in one still feeling the effects of antecedent inflammation. Another exciting cause is the abuse of irritating drugs, such as cathartics and tonics, or of medicinal substances which diminish the secretions and retard gastric peristole, as opium and cocaine. Many gastric diseases either predispose to chronic gastritis or excite it. Among these diseases are gastrectasia, suppurative gastritis, cancer and ulcer.

Morbid Anatomy.—The stomach, when affected by chronic inflammation, may be either normal in size, dilated, or smaller than in health. The pyloric region of the stomach is generally the seat of the most marked pathological changes. The mucous membrane is commonly abnormally vascular, and covered with a deposit of thick tenacious mucus, or of thinner muco-pus containing epithelial cells. The membrane may be thickened or thinned. In the earlier stages, there is more frequently general thickening and opacity, while diffuse thinning and transparency correspond to the atrophic changes of a later period in the disease. Thickening and thinning often, however, coexist, producing, by their combination, alternating prominences and depressions in the mucous membrane. This is the condition to which the name *état mamelonné* was given by Louis. Diffuse thickening of the pyloric mucous membrane may occasion stenosis of the pylorus, followed by gastrectasia. Small cysts, produced by the distention of obstructed gastric follicles with a clear fluid, are often observed, and, more rarely, polypi composed of hypertrophied connective tissue and hyperplasia of the gastric tubules. The consistency of the mucous membrane is, in some cases, increased, and in others diminished. The membrane is rough when thickening coexists with thinning, but it may be smooth when extensive atrophy exists alone. The color of the mucous membrane may be white, ashen, red, reddish-blue, slate-colored, reddish-brown, or black. Ecchymoses and so-called hæmorrhagic erosions are not rare, and many of the above-mentioned variegated tints are produced by the more or less complete reabsorption of hæmoglobin. Little points of a darker hue than the surrounding membrane are found, on microscopic examination, to consist of pigment particles, either free or inclosed in cells, between or within the tubules. The microscope generally shows, in the thickened parts of the mucous membrane, dilatation of the vessels, proliferation of connective tissue, sometimes hypertrophy of the submucous and muscular coats, and enlargement with distention of the gastric tubules, from parenchymatous and fatty degeneration of their epithelium. In the thinner portions of the mucous membrane the vessels are of small calibre. Some of the tubules are diminished in size, being filled with granular detritus resulting from degeneration of the epithelium, and others are quite obliterated by the pressure of surrounding, new-formed connective tissue. The cysts alluded to above are also due to partial obstruction of the tubules by connective tissue and their consequent distention with their perverted secretion. W. Fox has observed fatty degeneration of the connective tissue in some cases of chronic gastritis. The gastric solitary glands, when present, are often hypertrophied.

Clinical History. — Given the morbid anatomical changes of chronic gastritis, the symptoms of the disease are referable to certain perversions in the functional activity of the stomach. Chief among these is the interference with the normal secretion of gastric juice. The effects of the diminution of this fluid are the retardation of digestion and the occurrence of butyric, lactic, acetic, or alcoholic fermentation. These fermentations do not occur in a healthy stomach, because the normal gastric juice is capable of destroying the living ferments which cause these retrograde changes in the food. The acids generated by these fermentative processes, being themselves irritating, add to the existing inflammation, while the gaseous products of the fermentations overdistend the stomach, and retard the peristaltic movements of that organ by inducing atony of the muscular coats. The free acid of the gastric juice is, moreover, held, by many writers, to be an essential stimulus to the gastric peristole, and the absence of the normal quantity of this acid may, accordingly, be unfavorable to the production of natural gastric contractions. Since successive contact of the food with all parts of the mucous membrane is essential to the due stimulation of glandular activity, the delayed peristole itself further indirectly reduces the amount of gastric juice, which is already diminished by glandular degeneration and atrophy. Another bad result of the impaired contractile power is the prolonged retention of the undigested contents of the stomach, by which fuller opportunities for decomposition are afforded. The gastric mucus, which, in chronic gastritis, is secreted in abnormally large quantities, hinders digestion mechanically, by coating the food with a comparatively impenetrable material, and chemically, since its alkalinity partly neutralizes the acid of the gastric juice. It is well known that the bulk of peptones elaborated in the stomach are,

under physiological conditions, directly absorbed from that viscus. Chronic gastritis greatly impairs absorption by causing inefficient muscular contractions, and, probably, by leading to degenerative changes in the gastric absorbent vessels. It has, moreover, been demonstrated that the presence of unabsorbed peptones directly retards the further transformation of proteids into peptones. The individual symptoms of chronic gastritis will be better understood and more readily interpreted, if these deviations from the regular course of physiological gastric digestion be constantly borne in mind.

The morbid phenomena of chronic gastritis may be classified as subjective and objective.

(*a*) Subjective Symptoms. A prominent subjective symptom is the loss or the perversion of appetite. Usually there is indifference and often absolute repugnance to food. Sometimes, however, there is a morbid craving for stimulating foods and beverages. When the inflammation is of a comparatively low grade, there may even be a moderate appetite, which, however, is succeeded by a sense of repletion after the ingestion of a small quantity of food or drink. Thirst is an almost constant symptom, and is, usually, most troublesome in the evening. Patients commonly complain of a bad taste in the mouth and of dryness of the buccal mucous membrane. There is, generally, persistent epigastric discomfort, burning, or oppression, which is accompanied by tenderness, is most marked after meals, particularly if the food be stimulating, and may at times be replaced by more or less acute pain. Eructations, either acid or tasteless, pyrosis, nausea, and vomiting are common, taking place, most frequently, soon after meals. In mild cases vomiting does not often occur, and it is an unusual symptom in chronic gastritis complicating atonic gastrectasia. With habitual drinkers, morning vomiting is common, and is known to the laity as *water brash*. Headache is a prominent symptom. It is generally frontal or temporal, and of a dull character. At times it becomes acute, lancinating, and even excruciatingly severe. The other leading subjective symptoms are vertigo, fatigue, disinclination for either physical or mental labor, and generally great depression of spirits, sometimes amounting to hypochondriasis. These nervous symptoms are all probably the joint effect of anæmic neurasthenia and of auto-infection with ptomaïnes. The bowels are constipated, unless there be coexistent entero-colitis, in which case there may be diarrhœa. Flatulence is common. Hæmorrhoids are caused by the constipation. The sleep is disturbed by restlessness and by distressing dreams. The urine is scanty and high-colored, or the reverse in cases of long standing. There may be cardiac palpitation and so-called "hot flashes," from temporary facial and cerebral congestion. This symptom chiefly occurs in women. Dyspnœa may be occasioned by the encroachment of a tympanitic stomach upon the thoracic space.

(*b*) Objective Symptoms. The patients are, as a rule, more or less emaciated and anæmic, their muscles being atrophic and their expression apathetic or melancholy. The skin is dry and of a grayish tint, unless there be icterus from concomitant duodenitis, which is not rare. The tongue is commonly pale, flabby, and covered with a whitish or a brownish-white coat, through which enlarged papillæ may sometimes be seen. The tongue is occasionally red and glazed. The borders of the tongue sometimes bear the impress of the teeth. Salivation is common. The gums are pale and swollen, the breath fetid. The pulse is normal in frequency or slightly quickened. In old people, the pulse may be remarkably slow and feeble. It is generally small and compressible; it may be irregular and intermittent. There is often slight fever, particularly during the exacerbations of the symptoms corresponding to intercurrent attacks of more acute gastritis. The urine is, ordinarily, of a high specific gravity and of dark color, and is frequently laden with amorphous urates. Uric acid and oxalate of lime are common urinary deposits, and the mucus is often abnormally abundant. On the other hand, the urine may, in cases of long standing, be of low specific gravity and of a pale color, its reaction being neutral or alkaline, and its sediment containing amorphous and crystalline phosphates. The epigastrium is generally sensitive to pressure, and is often distended. A succussion sound may sometimes be obtained, even in an undilated stomach. Caries of the teeth has been noted by some authors. Considerable interest attaches to the character of the matters spontaneously rejected, or artificially withdrawn from the stomach. The microscope shows these matters to consist chiefly of mucus, gastric epithelium, and remnants of undigested food, with the occasional admixture of blood, saccharomyces, sarcinæ ventriculi and various bacteria. The reaction of the contents of the stomach is generally acid, from the presence of either hydrochloric, butyric, acetic, or lactic acid. The existence of hæmorrhagic erosion may be suspected if much blood be vomited. The presence of lactic acid may be demonstrated by means of a test-liquid composed of ten cubic centimetres of a four per cent. solution of carbolic acid, twenty cubic centimetres of distilled water, and a drop of liquor ferri perchloridi. The blue color of this mixture is changed to yellow by free lactic acid. Strümpell recommends a solution of methyl violet as a test for hydrochloric acid, which turns this reagent blue, and the same author makes favorable mention of Uffelmann's test, which consists of the pigment derived from the common blueberry or huckleberry. This pigment is turned a bright-red by free hydrochloric acid. The so-called "water-brash," rejected by habitual drinkers, is usually alkaline, and probably partly consists of saliva swallowed during sleep. In the chronic gastritis secondary to Bright's disease, traces of ammonium carbonate are found in the vomited matter. If it be deemed essential that the physician obtain definite data regarding the time consumed in digestion and the presence of the products of fermentation in the stomach, the gastric contents may be removed by a soft-rubber tube in the manner described in the section on Gastrectasia, six or seven hours after the ingestion of food. If undigested remnants of food are obtained, it is safe to assume the existence of impaired digestion, and diminished muscular power on the part of the stomach. By means of the tests given above, approximately accurate data relating to the relative amounts of hydrochloric and of lactic acid may be otained.

Differential Diagnosis.—Ulcer, cancer, dilatation of the stomach, and atonic dyspepsia may be mistaken for chronic gastritis. The differential points between the first three diseases and chronic gastritis will be found in the articles devoted to these subjects. Atonic dyspepsia presents few of the symptoms of irritation and none of the signs of inflammation characteristic of chronic gastritis. In dyspepsia there is hardly any febrile movement. In gastritis this occurs more frequently. In dyspepsia there is less often nausea and vomiting than in gastritis. In dyspepsia there is little thirst, in gastritis often tormenting thirst. In dyspepsia the tongue is often clean, in chronic gastritis almost always coated. In dyspepsia the appetite is generally good, and often ravenous, while anorexia is common in gastritis. In dyspepsia stimulating foods are best tolerated, in gastritis bland ones. In dyspepsia there is less gastric pain, tenderness, and burning than in gastritis. In dyspepsia the urine is generally normal, in chronic gastritis abnormal, containing urates, uric acid, and oxalates. In dyspepsia there is often no loss of weight, while emaciation is the rule in chronic gastritis.

Prognosis.—The duration of chronic gastritis, even when due to causes susceptible of removal, is long, particularly if the disease be wrongly treated or neglected. Relapses are common after apparent cures, and alternate with attacks of more acute gastric inflammation. Chronic gastritis dependent upon incurable diseases of other organs, as of the heart, lungs, or liver, is naturally not amenable to curative measures. Chronic gastritis is not in itself directly fatal, but, if protracted, may induce such a degree of asthenia as to incapacitate the patient for resisting intercurrent acute diseases, and may eventually lead to atonic or obstructive gastrectasia.

Treatment.—The treatment of chronic gastritis resolves itself into (*a*) the prophylactic, and (*b*) the curative treat-

ment. While the former has for its object the prevention of gastritis, the latter aims at fulfilling existing casual and symptomatic indications.

(*a*) Prophylaxis. The aggregate suffering caused by chronic gastritis is enormous, and preventive medicine finds in this disease one of its widest and most fruitful fields. It is the physician's duty to instruct the heads of the families intrusted to his care how to avoid all preventable causes of chronic gastritis, and these are enumerated in the writer's remarks concerning the etiology of this affection. Since recurrent attacks of subacute and acute gastritis strongly predispose to chronic gastritis, these should be carefully avoided. All remediable conditions causing anæmia and malnutrition must be removed, while incurable chronic diseases should receive appropriate palliative treatment. This remark is particularly applicable to diseases causing portal obstruction and consequent venous congestion of the stomach. Nearly all the exciting causes of chronic gastritis are avoidable if the patient only has sufficient moral force to control the cravings of appetite. The physician should, therefore, insist upon moderation in eating and in the use of alcoholic drinks, upon thorough cooking, upon the banishment of the elaborate products of the French *cuisine*, and upon the avoidance of drugs which irritate the stomach or check either its movements or its secretion.

(*b*) Curative Treatment. The indications for the curative treatment are causal and symptomatic. Existing predisposing and exciting causes are, if possible, to be removed, and physiological rest provided for the stomach. Thus, diseases of the heart, lungs, and liver, which lead to secondary gastritis, are to be relieved, and the labor of digestion reduced to a minimum. Even in a mild case it is desirable to adopt simple measures for cleansing the stomach of mucus and of undigested food. This may generally be efficiently accomplished by the use of a large glass of warm or cool water on retiring, and again in the morning, as long as possible before the first meal. The benefit resulting from this measure is referred to the cleansing and quieting effect of the water, which carries away much of the accumulated mucus and any residue of undigested food into the intestine. Sometimes laxative enemata, with water taken as above suggested, suffice to produce efficient alvine evacuations. A seidlitz powder may, however, be given, at first every morning or every second morning, to clear the intestine of undigested food and of accumulated mucus. Should this not prove sufficient, two grains of calomel triturated with milk-sugar may be administered every second evening. Careful and explicit dietetic rules must be framed for each patient in accordance with his personal necessities, for while the principles directing the treatment of all cases are the same, allowance must be made for individual idiosyncrasies and for varying physical conditions. All irritating foods and drinks are to be absolutely forbidden. This rule excludes very hot or very cold articles, alcohol, spices, condiments, and decided acids, which are chemically irritating, and all bulky, rough, or indigestible aliments, which mechanically excite the inflamed mucous membrane. All readily fermentable foods are, at first, to be withheld. In this category must be placed the sugars, starches, and fats, whether alone or in the form of cakes and pastry, where they are found in proverbially fatal combinations. Cooked fats seem particularly indigestible, while small quantities of cream and butter are sometimes well tolerated. Even uncooked fats, however, impede gastric digestion by encasing other foods in a covering more or less impenetrable to the watery gastric juice. The best food for the great majority of cases is milk. Sweet milk may be given undiluted, or diluted with pure water or with Vichy water, the proper proportions of each being determined by experiment. The writer commonly begins with one-fourth Vichy water and three-fourths milk, gradually decreasing the proportion of Vichy water. If sweet milk is not well tolerated, it may be peptonised, or butter-milk may be tentatively employed. Whichever variety of milk is selected ought, in the writer's opinion, to be persistently employed until the subsidence of the graver symptoms betokens relief of the inflammation. The quantity of milk should be about two quarts in the twenty-four hours, and the intervals at which it is taken may vary from two to four hours. Should milk, in any form, be so repulsive to the patient that his repugnance cannot be overcome, Leube-Rosenthal's meat solution may be substituted. In the intervals between the feedings thirst may be allayed by frequent sips of cool water or of carbonated water. When nausea, thirst, and fever have disappeared, more solid foods are gradually to be added to the *menu*. Those most likely to be tolerated are soft-boiled eggs, cold roast mutton, and stale bread well toasted. With these solids small quantities of weak tea or of weak *percolated* coffee, without sugar, may be used as beverages. The quantity of solid food at first employed must be smaller, and the meals more frequent, than in health. The patient should be impressed with the absolute necessity of very slow and thorough mastication. At a more advanced stage of convalescence other meats, such as roasted, broiled, or boiled mutton, tender broiled beefsteak, as well as broiled oysters and tender chicken, may be used. Rare roast beef may, finally, be taken in small quantities, preferably finely scraped and seasoned only with salt. A little rice, well boiled, may next alternate with the toast, and, finally, other vegetables may be tried. The best vegetables are well-boiled rice, baked potatoes, tender carrots, very young pease and tender asparagus. The length of time during which this treatment must be carried out can only be determined by experiment in each case. The least symptom of a relapse, during the use of solid food, should serve as a warning that the milk diet is to be resumed for a season.

Few *drugs* are necessary in the treatment of this disease. Since the gastric juice is deficient in chronic gastritis, it may well be replaced by pepsine and hydrochloric acid. The former may be exhibited in five-grain doses, after each meal. The acid is best administered in doses of from five to ten drops, from one-half to one hour after food. If there be notable acidity of the stomach, as proven by cardialgia and acid eructations, a few grains of sodium bicarbonate may be given before each drink of milk, or before each solid meal. Should the stomach be unusually sensitive to pressure, twenty or thirty grains of the subcarbonate of bismuth may be combined with the soda. If epigastric sensitiveness be extreme, emesis common, or pain severe, small doses of hydrocyanic acid, cocaine, codeia, morphia, or hyoscyamus may be exhibited. In all cases counter-irritation of the epigastrium is good, and, in obstinate cases, even moderate vesication. Constipation is to be relieved by small doses of calomel triturated with sugar, given every second evening, and followed the next morning, if necessary, by a small dose of Hunyadi Janos water, or by a seidlitz powder. The saline laxatives act best on an empty stomach, and their effect is more speedy and complete if they are given warm. Should there be marked gastric tympanites, thirty-grain doses of pure willow charcoal will be found useful as an absorbent of the gases. It is, however, more rational to prevent the fermentations causing gaseous accumulations by decreasing the amount of food and by increasing the pepsin and hydrochloric acid. Antiseptics are rarely necessary, but naphthaline, in five-grain doses, has, in the writer's experience, quickly relieved gastric tympanites not readily controlled by other means. Salicylic acid and the sulphites have been found equally efficient, but more irritating. Intestinal tympanites is commonly easily overcome by salol, in doses of from two and a half to five grains, administered at intervals of from two to four hours. The bad taste in the mouth is greatly diminished by thoroughly cleansing the tongue with a soft rag or brush, and by lotions containing a few drops of the tincture of myrrh, or a few grains of carbolic acid to the ounce. When epigastric tenderness has quite disappeared, a bitter tonic, preferably the tincture of nux vomica, or the infusion of gentian, may be sparingly used to restore tone to the weakened stomach. Anæmia is to be combated by the mildest ferruginous preparations. After complete subsidence of the gastric symptoms, habitual constipation may be relieved by

small doses of aloes and rhubarb in combination, or by a pill composed of aloin, $\frac{1}{6}$ grain ; strychnine, $\frac{1}{100}$ grain ; and extract of belladonna, $\frac{1}{8}$ grain. Great attention should be also paid to general hygiene, all patients being constrained to keep early hours, to lead lives so far as possible free from excitement, and, above all, to exercise moderately in the open air. The clothing should be warm, and the functions of the skin should be maintained by cool sponge-baths. In obstinate cases, washing the stomach is a measure of inestimable value. By this method the stomach is at once relieved of accumulated mucus, undigested aliment, acids and gas. The use of hot or cold water and of cathartics is thus, in a large measure, obviated, and the bowels may be relieved by enemata. The writer's method of employing *lavage* is given in the section on Gastrectasia. Lavage is, at first, best performed every morning, an hour before breakfast. After a short time the washing may be done every second morning, and then, at lengthening intervals, until convalescence is established. In cases requiring the use of the tube, the other therapeutic measures are, in general, identical with those already described as applicable to less severe cases of chronic gastritis. In the most refractory and chronic cases it may be necessary to temporarily resort to rectal alimentation, in the manner recommended under the caption Acute Gastritis. The efficacy of the above treatment, systematically followed, is generally quickly manifest in the relief of symptoms, in the augmentation of weight and in the increase of mental and of bodily energy.

SUPPURATIVE GASTRITIS. *Definition.*—Primary or secondary suppurative inflammation of the stomach, usually affecting the submucous tissues, but sometimes involving other coats of the organ.

Etiology.—The causes of primary suppurative gastritis, which is very rare, are not well known. The disease affects men more often than women, and middle-aged persons rather than the young or the aged. It has been referred to traumatism, gastric ulcer, the abuse of alcohol and to dietetic indiscretions. Silcock reports a case following gastrostomy. In many cases no adequate cause has been ascertained. Secondary, or metastatic, suppurative gastritis, which is more frequent than the primary form, occurs as a complication of acute infectious diseases, especially of puerperal septicæmia and pyæmia.

Morbid Anatomy.—The suppuration may be either circumscribed or diffuse. The former variety is known as abscess of the stomach, which may be single or multiple. It is less rare than diffuse suppurative gastritis. In gastric abscess the pus first collects in the submucous tissues, whence it sometimes makes its way between the muscular layers and into the subserous tissue, or may even perforate the mucous and serous layers, pus being then evacuated into the stomach or into the peritoneal cavity. The abscess is sometimes, however, confined to its original seat in the submucous tissues. If the serous coat is involved, general peritonitis may follow. Exceptionally the abscess cavity may close after the escape of its contents, and cicatrization, occurring, may lead to gastric stenosis. In diffuse suppurative gastritis the pus is also first formed in the tunica submucosa, whence it may invade the intermuscular connective tissue, the subserous structures, the mucous membrane, and the serous coat. In rare instances the inflammatory process is, however, confined to the submucosa. The suppuration commonly involves only a part of the gastric parietes, but it may be coextensive with them, and may even invade the duodenum and the œsophagus. Diffuse and circumscribed purulent gastritis sometimes coexist. The parts of the stomach affected are swollen, and the mucous membrane over the seats of purulent collection is œdematous and spongy, or perforated and ulcerating. The ulcers may be single or multiple. There may be evidences of pre-existing chronic gastritis or of fibroid gastritis. The serous coat frequently becomes inflamed, and general peritonitis may be the result. Thrombi sometimes form in the veins of the stomach, and parts of the thrombi, becoming detached, produce metastatic abscesses of the liver and of the lungs. The microscopical examination of the purulent matter often shows numerous streptococci and other bacteria.

Clinical History.—Primary suppurative gastritis may be acute or chronic. In either case the symptoms are the same, except in their duration. The initial symptom is generally a chill, which may or may not be repeated at irregular intervals. Fever follows, with a rapid compressible pulse and a high temperature, scanty urine, tormenting thirst, headache and anorexia. There is generally much nausea and vomiting, as well as great epigastric pain and tenderness, with meteorism, although these features are not invariably present. The vomited matter sometimes contains pus, but ordinarily only mucus, gastric juice, or bile. Sometimes a tumor, corresponding to an abscess, may be felt in the wall of the stomach. If the abscess ruptures into the stomach, large quantities of pus may be vomited. If perforation occurs into the peritoneal cavity, symptoms of shock appear and are followed by those of acute peritonitis, if the patient survives a sufficient length of time. Jaundice is sometimes present, and there may be either diarrhœa or constipation. Asthenia appears early in the disease and deepens into collapse, death being commonly preceded by delirium and coma. Secondary suppurative gastritis presents essentially the same symptoms, but they are generally completely masked by those of the primary complaint (*vide* article Septicæmia and Pyæmia, in this HANDBOOK).

Callow's case, recited by Leube, presented no symptoms up to the day of its fatal termination, when rupture of the gastric abscess took place, emesis occurred, and speedy collapse followed.

Diagnosis.—The diagnosis can rarely be made during life, although the disease may be strongly suspected when, coincidently with the existence of the above symptoms, a soft gastric tumor is felt, which suddenly disappears simultaneously with the vomiting of a large quantity of pus. Circumscribed suppurative peritonitis might, however, present almost identical symptoms.

Prognosis.—This, although very grave, is not absolutely desperate, as some apparently authentic cases of recovery have been reported. Death usually ensues in about a week, but life may, in cases eventually fatal, be prolonged three weeks or longer.

Treatment.—The treatment is purely symptomatic. Pain and emesis are to be relieved by the hypodermic use of morphine, rest of the stomach secured by rectal alimentation, and the strength sustained by fearless stimulation. Some authors recommend the persistent application of ice to the epigastrium, and the administration of small ice-pellets by mouth. In secondary suppurative gastritis the primary disease naturally claims appropriate treatment.

CHRONIC INTERSTITIAL GASTRITIS AND HYPERTROPHIC PYLORIC STENOSIS. *Definition.*—Thickening of the stomach, either general or limited to the pyloric region, due chiefly to the development of new connective tissue, with which hyperplasia of the muscular coat is usually associated.

Etiology.—Cases of this disease are so rare that few opportunities have been afforded for the discovery of its causes. It affects middle-aged men most frequently, but has been observed in young men, in women, and, very rarely, in children. Chronic interstitial gastritis is often associated with simple chronic gastritis, but there is no proof that it is produced by the latter disease. The abuse of alcohol is regarded as an exciting cause by the majority of authors, but the circumstances under which alcohol leads to this form of gastric inflammation, rather than to chronic gastritis, are not definitely known. Welch observed a case in which there were syphilitic gummata of the liver, and Snellen reported a case in which the disease followed an injury to the epigastrium. Many cases of hypertrophic pyloric stenosis are believed to owe their origin to the cicatrization of a gastric ulcer. Others are without evident cause.

Morbid Anatomy.—The pathological changes may affect the whole stomach equally, or they may be most marked at the pylorus. When the whole stomach is involved, the organ is generally heavier and smaller than

normal. The capacity of the stomach may be reduced to a few ounces, and its size to that of a small pear, which fruit it somewhat resembles in shape. The gastric wall has, in some recorded cases, been more than an inch thick. The dimensions of the stomach may, however, be either normal or abnormally large. Upon section the stomach sometimes does not collapse as in health, owing to the thickness and firmness of its walls, the consistency of which often resembles that of cartilage. The minute examination of the tunics of the stomach shows all the coats of the organ to be structurally altered by that growth of new connective tissue which is characteristic of the disease. The submucous tissues are usually most involved, and the submucosa thus stands out upon cross-section as a broad, firm, whitish layer. The mucous membrane sometimes escapes alteration, but generally the microscope shows the gastric tubules to be compressed, or even obliterated, by hyperplasia of the intertubular connective tissue. In this case, the cellular elements present the same microscopical changes found in simple chronic gastritis (*quod vide*). The muscular layer is often greatly thickened, particularly in its transverse fibres, by hyperplasia of the muscular fibres and of the interfibrillary connective tissue. The subserous and serous coats are similarly thickened, the latter being opaque and of a milky-white color. The entire peritoneum may, rarely, present a similar thickening, or only the visceral layer may be affected. Welch states that adhesions frequently exist between the stomach and surrounding organs. When the above-described interstitial changes involve only the pyloric region, hypertrophic stenosis of the pylorus is said to exist. The result of these localized pathological processes is, as the above name implies, a more or less complete occlusion of the pyloric orifice. Owing to the obstacle opposed to the escape of the gastric contents, the latter accumulate, and, overdistending the stomach, produce gastrectasia, to which is added hypertrophy of the muscular coat.

Clinical History.—The symptoms of chronic interstitial gastritis are variable and ambiguous. In some cases there have been no symptoms, or these have been of so trivial a character that they have been referred to functional dyspepsia. In a case reported by Nothnagel the disease presented the characteristic features of pernicious anæmia. If the disease involves the entire stomach, one somewhat characteristic symptom, at a late stage of the malady, may be inability on the part of the patient to take more than a very limited amount of food or drink without a disagreeable sensation of distention referred to the epigastrium. At this advanced period of the disease the hardened and contracted stomach may be recognized by abdominal palpation, presenting the peculiar form and outline of the normal organ. In such a case the exact capacity of the stomach may be ascertained by first removing all the gastric contents with the soft tube, and then introducing water from a graduated receptacle until a sensation of discomfort is perceived. Before the development of the symptoms mentioned there may be those of a protracted chronic gastritis—vomiting, emaciation, and asthenia being particularly prominent clinical features, while pain is almost or quite absent. Sometimes there is, however, violent gastralgia. In that form of chronic interstitial gastritis known as hypertrophic stenosis of the pylorus, the clinical history corresponds to that of obstructive gastric dilatation, to which the reader is referred. The symptoms of dilatation are sometimes preceded by those of chronic gastritis. The hypertrophic pylorus can occasionally be made out by abdominal palpation, and is apt to be mistaken for a carcinomatous tumor.

Differential Diagnosis.—Diffuse chronic interstitial gastritis is to be distinguished from simple chronic gastritis. The distinction can only be made with an approach to certainty when, in the later stages of the disease, a contracted and hardened tumor, presenting the contours of the stomach, can be mapped out.

Hypertrophic stenosis of the pylorus may be mistaken for atonic dilatation of the stomach and for cancer. The differential points between hypertrophic stenosis of the pylorus and atonic dilatation are stated in the section on Gastrectasia. Cancer can, generally, be excluded by attention to the following points: Patients with carcinoma have almost always passed middle life, while stenosis of the pylorus may affect the young. In cancer there is often a family history pointing to that disease. In hypertrophic stenosis this is not true. In cancer the duration of the disease is short, usually under two years; in hypertrophic stenosis it may be long. In cancer there is commonly much pain; in stenosis there is generally little or none. In cancer hæmatemesis is common, but it is rare in simple stenosis. In cancer there is a peculiar cachexia, which is absent in hypertrophic stenosis. In cancer there may be secondary hepatic carcinomata, while metastasis does not, of course, occur in stenosis. In cancer the tumor is tender on pressure, while in hypertrophic stenosis it is not so.

The *prognosis* of chronic interstitial gastritis, of either form, is serious, the patients ordinarily succumbing to inanition and asthenia.

The *treatment* of chronic interstitial gastritis, when diffuse, embraces the exclusion of all irritating ingesta, the use of bland, and, if necessary, of predigested foods, given in small quantities and at frequent intervals, and the employment of rectal alimentation. In cases of hypertrophic stenosis of the pylorus the treatment is the same as that recommended in the following section on Gastrectasia.

Dilatation of the Stomach (Gastrectasia). *Definition.*—That condition of the stomach in which the organ is both abnormally capacious and inadequate to the performance of its functions, *i.e.*, the digestion and absorption of some foods and the propulsion of other alimentary materials into the intestine. Two forms of gastrectasia are recognized, namely, hypertrophic dilatation, in which the gastrectasia is preceded or accompanied by muscular hypertrophy, and atonic dilatation, in which no compensating hypertrophy occurs.

Etiology.—The classification of the causes producing gastrectasia, suggested by Professor William H. Welch (Pepper's "System of Medicine," vol. ii., p. 591, edition 1885), is so clear and comprehensive that the writer introduces it in this place. The three causative conditions recognized in Professor Welch's classification are: I., Stenosis of the pylorus and of the duodenum; II., abnormalities in the contents of the stomach; and III., impairment of the muscular force of the stomach. These general causative conditions may be again subdivided into the following tabulated classes. It will be noticed that causes belonging to Class I. occasion dilatation with hypertrophy, while those of Classes II. and III. lead to atonic dilatation.

I. Stenosis of the Pylorus or of the Duodenum. 1, Cancerous; 2, cicatricial; 3, hypertrophic (of pylorus); 4, from external pressure; 5, congenital (of pylorus) (?); 6, from torsion of duodenum.

II. Abnormalities in the Contents of the Stomach. 1. Ingesta: (*a*) Excessive; (*b*) imperfectly masticated; (*c*) indigestible. 2. Stagnation and fermentation in consequence of chemical insufficiency of the stomach, as in chronic catarrhal gastritis and functional dyspepsia.

III. Impairment of the Muscular Force of the Stomach. 1. Organic changes in muscular coat: (*a*) Partial destruction by ulcers and cancers; (*b*) inflammation, as in chronic catarrhal gastritis and peritonitis; (*c*) degenerations (fatty, colloid, amyloid); (*d*) œdema (?); (*e*) cirrhosis of stomach. 2. Mechanical restraint: (*a*) By adhesions; (*b*) by weight of herniæ. 3. Impaired nutrition and general muscular weakness, adynamic dilatation from typhoid fever, tuberculosis, anæmia, etc. 4. Paresis from neuropathic causes (?).

Obstruction at the pylorus, or near that orifice, in the duodenum, is the most important cause of gastrectasia, which is, generally, of the hypertrophic variety, *i.e.*, accompanied by hypertrophy of the gastric muscles. Hypertrophy of these muscles may, however, sometimes quite compensate the obstructive lesion, in which case gastrectasia does not ensue. In almost all cases of hypertrophic gastrectasia the order of events is as follows:

First, obstruction, then compensatory hypertrophy without dilatation, and, finally, hypertrophic dilatation in which the dilatation eventually preponderates.

I. Stenosis of the Pylorus or of the Duodenum. Pyloric stenosis is more frequently due to cancer than to any other morbid condition, and the next most frequent cause is contraction of cicatrices resulting from pyloric gastric ulcers. Duodenal stenosis, leading to dilatation of the stomach, may also be brought about by cicatrices and tumors of that part of the intestine or by external pressure. Under the caption Chronic Interstitial Gastritis it has been stated that this disease, when limited to the region of the pylorus, may cause obstruction of that orifice, and stenosis may, very rarely, be caused by sarcomata, myomata, fibromata and other benign tumors. The most common causes of stenosis from external pressure are tumors, such as hepatic carcinomata, and contracting cicatricial bands resulting from circumscribed peritoneal inflammation. The question of the existence of congenital pyloric stenosis is still *sub judice.* Landerer reported ten cases of supposed congenital stenosis of the pylorus, but his conclusions regarding their congenital character have not been generally accepted. Torsion of the pylorus or of the duodenum, or traction upon these parts by complete inguinal hernias, particularly by those containing the transverse colon or the omentum, may lead to stenosis of the intestine, and to secondary gastrectasia.

II. Abnormalities in the Contents of the Stomach. These abnormalities relate either to the character of the gastric contents or to unnatural fermentations in the food. Ingesta may be abnormal in quantity, in quality, or in their preparation. Vegetable foods, if relied upon to the exclusion of animal diet, may induce dilatation because of the large volume of aliment required, and liquids, as ice-water or beer, may act in the same way, when ingested in considerable quantities. Foods which are difficult of digestion, either because not easily penetrated by the gastric juice or because readily fermentable, may cause atonic dilatation ; and the same is true of raw and of imperfectly cooked aliments, and of those not thoroughly masticated and insalivated. It is possible that the long continued abuse of drugs which diminish the secretions of the stomach, or which inhibit its peristole, may also contribute to the development of atonic gastrectasia. Atonic dilatation is, moreover, often brought about by repeated attacks of indigestion and of gastritis, which favor the retention and decomposition of the contents of the stomach. In these cases both the secretion and the peristaltic movements are inhibited, and abnormal fermentation is the inevitable result. Fermentation leads to the evolution of gases which distend the stomach, and of acids—chiefly acetic, butyric, lactic and hydrosulphuric acids—which by their irritating character aggravate the pre-existing inflammation.

III. Impairment of the Muscular Force of the Stomach. Diminution in the muscular power of the stomach may be due to the various organic lesions of the gastric parietes enumerated in the above table. The weakening effect of chronic gastritis and of peritonitis has been already alluded to. Ulceration, whether simple or carcinomatous, and of varying depth, may diminish the stomach's contractile power, as well as amyloid, colloid and fatty degeneration of the gastric muscles, and the changes incident to chronic interstitial gastritis. Among the remaining tabulated causes of atonic dilatation should be emphasized the general weakness and atony of all the bodily tissues, resulting from anæmia, acute febrile diseases and chronic wasting affections. Fenwick refers to a case, reported by Willis, in which primary paralysis of the stomach followed an injury to the splanchnic nerve. It is often quite impossible to assign a single definite cause for the occurrence of dilatation in an individual case, as several etiological agents are almost certain to co-operate in its production. This is particularly true of gastritis, muscular insufficiency, and fermentation, which most frequently go hand in hand, and which are, to a large extent, interdependent. Diabetic patients suffer from gastrectasia on account of the polyphagia characteristic of their primary disease, and a sedentary life, combined with a generous diet, has the same result. Hypertrophic dilatation of the stomach is most frequent after middle life, because cancer, the chief cause of this variety of gastrectasia, develops at that age. Atonic dilatation is most common in middle life, but may occur at any age. When occurring in childhood it particularly affects rachitic children.

Morbid Anatomy.—While the *post-mortem* recognition of largely dilated stomachs presents hardly any difficulty, that of slightly and of moderately dilated stomachs may be impossible, because of the wide limits within which the size of the normal organ varies. If a reliable history can be obtained, the clinical test of gastrectasia, viz., inability of the stomach to empty itself, may be utilized in making a *post-mortem* diagnosis. Even when the stomach reaches below the umbilicus, it is not necessarily dilated. Perfectly normal stomachs, which are of a looped shape, or which occupy a vertical position such as exists in fœtal life, may extend considerably below the navel. A. Flint, Sr., states that tight-lacing may depress the stomach to a notable extent. The size of a dilated stomach may, on the one hand, be so small that the clinical test of insufficiency is necessary to render the diagnosis at all certain, or, on the other hand, may be such that the stomach contains gallons of liquid, occupies nearly the whole abdomen, and reaches nearly or quite to the iliac bone. Cases have been reported in which the dilated organ descended even into the true pelvis, or into the sac of a complete inguinal hernia. Stomachs which are the seat of hypertrophic dilatation from obstruction are generally of larger dimensions than those affected by atonic dilatation. The fundus becomes first dilated, and although the entire organ may subsequently be involved, the fundus remains more largely dilated than the cardiac and the pyloric extremities. The increased weight of the dilated stomach generally causes it to be displaced downward, the pylorus occupying a lower plane than normal and dragging the duodenum downward from its natural position. The stomach thus sometimes comes to assume a more vertical position than that of health. If, however, the pylorus be fixed, as in cancer, the long axis of the organ is more nearly transverse than normal, owing to the predominant dilatation of the fundus. In the early stages of gastrectasia from obstruction, the walls of the stomach are generally notably thickened, especially at the pylorus, by hyperplasia of the muscular coat. At a later period of the disease the gastric parietes may be found normal in thickness, or even decidedly thinned In non-obstructive gastrectasia the muscular coat may be hypertrophied, but it is commonly atrophied. In both varieties of gastrectasia fatty degeneration of the muscular fibres, and a pathological condition described by Maier as colloid degeneration of these fibres, is not very rare. The mucous and other coats of the stomach ordinarily present in dilatation the changes already described as characteristic of chronic gastritis. In addition to the morbid anatomical changes peculiar to dilatation, those of the primary disease, which has occasioned gastrectasia, will be observed. These primary pathological conditions are enumerated in the preceding etiological table. If the gastrectasia be caused by duodenal obstruction, this part of the bowel will be likewise dilated. The œsophagus is often dilated in pronounced cases of gastrectasia. The liver, spleen, intestine, diaphragm and heart are sometimes displaced by the enlarged stomach. The spleen, liver and pancreas are frequently atrophied. Many writers refer these atrophic changes to the pressure of the stomach, but they are, more probably, merely subordinate features of the general emaciation resulting from gastrectasia. The pressure of indigestible foreign bodies, such as coins or bits of wood, is said by Leube, when long continued, to have occasionally produced circumscribed or sacculated dilatation of the stomach. .

Clinical History.—The symptoms presented by patients suffering from gastrectasia are referable partly to the original causative conditions of the disease, and, partly, to the dilatation proper. The symptoms due to the causes which eventually produce gastrectasia, may exist for a long time before the supervention of those denoting dila-

tation, and, if properly interpreted, may thus afford an indication for the adoption of preventive treatment. The symptoms, which are to a certain extent premonitory, as well as concomitant, are usually those of carcinoma or of ulcer in cases of hypertrophic gastrectasia, and of chronic gastritis in the early stages of atonic dilatation. These symptoms need not be enumerated in this place, as they are given in this article under their respective headings. Among the symptoms properly referred to dilatation, but which do not occur in hypertrophic gastrectasia so long as compensation is complete, the most prominent is copious vomiting at irregular intervals. This symptom is almost constant in dilatation from obstruction of the pylorus or of the duodenum, and is also frequent in the earlier stages of atonic gastrectasia. When, in either class of cases, the gastric nerves and muscles have partly sacrificed their functional powers, owing to compression, atrophy, or degeneration, emesis becomes less frequent and may entirely cease. The most characteristic features of this vomiting are its copiousness and its tendency to a more or less periodical recurrence. The volume of vomited matter often far transcends the normal capacity of the stomach, sometimes amounting to several quarts. The length of time intervening between successive acts of emesis varies with the irritability of the stomach and with the amount ingested. Two, or even more days, however, generally intervene between the paroxysms of vomiting, but the interval may be of only a few hours' duration. The emesis commonly occurs several hours after meals, and is frequently explosive, being unaccompanied by notable straining. The vomiting does not completely empty the stomach, which is often found still largely distended after the emesis has ceased. The vomited matters consist largely of undigested food, which fact may be ascertained by macroscopical inspection. In some instances portions of aliment taken days before their rejection may be recognized. Their odor is that of putrefaction. Their reaction is acid, from the presence of lactic, acetic, and butyric acids, or, rarely, from that of gastric juice. Their color varies with their composition. When the diet has been a mixed one, the color is generally yellowish, or brownish-red. Sometimes it is almost black or gray, with interspersed clumps of a blackish color. The upper layers of the vomited matters are often white and frothy. Strings and shreds, apparently of muco-pus, are dependent from this layer, reaching for some distance below the surface. At the bottom of the vessel are seen irregular masses of solid material.

Microscopically examined, the vomited matter is found to contain food particles, either undigested or but partly digested, bacilli and other bacteria, sarcinæ ventriculi, torulæ cerevisiæ, and other fungi or their spores, crystals of fatty acids, flat epithelium from the stomach and œsophagus, mucus, pus, and occasionally blood-corpuscles. Sometimes hæmatin is detected by chemical tests, when no blood-corpuscles can be recognized, and bile may be present in sufficient quantity to furnish its characteristic chemical reactions. Blood is more frequently found in cases of gastrectasia from cancer than in simple atonic dilatation, while bile is more often present in atonic gastrectasia. Various gases are held in solution in the vomited matters. Chief among these gases are oxygen and nitrogen, in about the same proportions as in the atmosphere; sulphuretted hydrogen, hydrogen and carbonic dioxide. In a case observed at Frerich's clinic, olefiant gas and some undetermined gaseous hydrocarbons were present. In this case the gases burned with a yellow flame. In other, comparatively rare, instances, the gas burns with a whitish flame. The gases in question mostly result from the abnormal fermentations in the stomach, but the nitrogen and oxygen may be swallowed with the food. Acetic, butyric, lactic and hydrochloric acids are at times present. These, with the exception of the last, result from fermentative processes. The clinical test of gastrectasia consists in the habitual discovery, among matters rejected from the stomach by vomiting, or withdrawn by the stomach-tube, of food taken on the preceding day, or even earlier. Subacute or chronic gastritis may cause the retention of food for an equal length of time; but, if this test be habitually successful, the existence of gastrectasia may be confidently assumed. The error is sometimes committed of considering stomachs of unusually large size, as shown by physical examination, to be dilated. The weight of authority is, however, in favor of regarding only those stomachs as dilated which, independently of their capacity, are inadequate to the performance of their digestive and propulsive functions.

Physical Signs.—Inspection of the abdomen sometimes reveals unusual prominence of the epigastric, of the left hypochondriac, and sometimes of other abdominal regions. If the abdominal walls are thin and relaxed, the outlines of the dilated stomach may be distinguished and the peristaltic gastric movements studied. This peristole may occur spontaneously, or may require to be excited by percussion and pressure. The movements begin at the cardiac extremity of the organ and slowly pass toward the pylorus. Rarely they alternately progress in either direction. These peristaltic movements are commonly indicative of hypertrophic dilatation, but that they are not characteristic of gastrectasia alone is shown by their occasional occurrence in healthy stomachs. Kussmaul refers such visible movements, occurring independently of gastrectasia, to a neurosis of the stomach. Similar vermiform movements in the intestine may simulate those of the stomach. If, while the abdominal protuberance is under observation, about thirty grains of sodium bicarbonate and fifteen grains of tartaric acid, in separate solutions, be drunk in quick succession, as recommended by Frerichs, sufficient carbonic dioxide may be generated to more fully distend the stomach, and thus to render its outline more clearly apparent. In widely dilated stomachs a much larger quantity of these reagents may be necessary to efficiently distend the stomach. This method of distending the organ is not uniformly successful, inasmuch as the gas may sometimes escape into the intestine, through a relaxed pylorus, almost as rapidly as it is generated. The method has, besides, the disadvantage of occasionally distending the stomach to such an extent as to cause severe pain. In such an emergency the prompt introduction of the stomach-tube is indicated, and quickly affords relief. Some authors advocate the employment of distention with gas, when the stomach is empty, to demonstrate the extent of the dilatation, but the method is open to so many objections that its usefulness is problematical. Even a healthy stomach may be distended to a misleading extent through the rapid generation of gas by the method in question, and in an organ the walls of which are relaxed by disease, the results would be still less reliable. Were the supposed gastrectasia due to malignant disease, the friability of the gastric walls might be such that rupture would occur from overdistention with the gas.

Palpation may sometimes enable the examiner to outline the borders of a dilated stomach, to obtain fluctuation and to perceive the peristaltic gastric movements. If the stomach be not overdistended with liquid, palpation may also elicit a splashing sound in the organ, which is, however, generally more readily produced by gentle succussion of the entire abdomen. If succussion be resorted to, the patient is requested to lie upon his back and to relax his abdominal muscles. The physician then grasps the iliac bone and the lumbar region with either hand, the thumbs being directed forward, and imparts a quick, lateral, vibratory motion to the body, simultaneously applying his ear to the epigastrium. This succussion sound is only diagnostic of gastrectasia when obtained six or eight hours after a meal, or from three to four hours after the ingestion of liquids, as it is often heard, under other circumstances, in perfectly healthy stomachs. Some persons can produce it at will, by rapid movements of the diaphragm, by holding the breath and quickly contracting the abdominal muscles, or by simply changing their position. The gastric succussion sound may be almost perfectly simulated by a like splashing sound in the transverse colon. An accessory diagnostic measure, suggested by Leube, consists in feeling, through the abdominal

wall, the end of a hard stomach-tube introduced into the stomach. If the tube be felt far below the umbilicus, dilatation is, according to Leube, probably present. This method is, however, not to be recommended, since the hard tube may inflict injury upon the gastric wall, and, even when introduced, cannot always be recognized with certainty. Oser objects to Leube's method because the sound may slip along the greater curvature, and, bending upward, may even reach the pylorus, so that its point will be felt far above the most dependent part of the stomach. Palpation may show upward displacement of the heart, and cardiac arhythmia if the stomach is greatly distended with gas.

Auscultation, besides aiding in the detection of the gastric succussion sound, may reveal the presence, in the stomach, of fine crackling or hissing sounds, produced by the bursting of minute bubbles of gas upon the surface of the liquid contents of the stomach. This gas, as already explained, owes its origin to abnormal fermentations.

Percussion often affords great assistance in mapping out a dilated stomach, but, in other cases, the information it conveys is negative or misleading, from the fact that intestinal tympanites may displace the greater curvature upward or may overlap the stomach to a variable extent. Over a stomach which is considerably dilated, and contains liquid and gas, there is, when the patient is erect, a tympanitic percussion note above the level of the liquid. The line of flatness is changed, when the patient assumes the dorsal or the lateral decubitus, to that part of the viscus which is the most dependent, while the tympanitic resonance is heard over the highest point of the stomach. The most rational method of ascertaining the existence and the extent of dilatation is, in the writer's opinion, that referred by Welch to Penzoldt. This method consists in withdrawing all fluids from the stomach by the tube, whereupon the pre-existing flatness disappears. If, now, a moderate quantity of liquid, from a pint to a quart, be introduced through the tube, flatness will reappear. If the flatness extends below the umbilicus, dilatation exists, and the extent of the gastrectasia may be approximately ascertained by noting the lowest level reached by the liquid.

General Symptoms.—The bowels of patients suffering from gastrectasia are generally obstinately constipated, because a comparatively small amount of aliment gains access to the intestine within a given time, and the fæcal matter is soon deprived of its fluid constituents by the intestinal absorbents. The bile and the intestinal juice are also reduced to a minimum, and intestinal peristole is consequently retarded. Sometimes diarrhœa alternates with constipation, and is best explained by the assumption that occasional relaxation of the pylorus allows the entrance of a large volume of undigested and fermenting matter into the bowel. The tongue may be either coated or clean. A coating speaks for the existence of gastritis. The urine is usually acid, scanty, high colored, and of high specific gravity, either from retention of liquids in the stomach or as a result of coincident gastritis. The urinary sediment is often abundant, and contains, chiefly, amorphous urates and oxalate of lime. In gastrectasia uncomplicated by gastritis, the specific gravity may be low and the reaction neutral or alkaline. In this case, amorphous phosphates and crystalline phosphates of lime and magnesia may be precipitated. Quantitative analysis has revealed a relatively small quantity of urea and a large amount of phosphates in many of the writer's cases. The pulse is apt to be slow and feeble, the surface cool and dry, or clammy, and the temperature normal. Owing to the lowered vitality, the temperature may be subnormal during the early morning hours. Intercurrent attacks of subacute or of acute gastritis may reverse these conditions, and the pulse may sometimes become irregular, fluttering, frequent, and intermittent from disturbed cardiac action due to the pressure upon the thoracic viscera of a stomach distended with gas. Gastric tympanites may also induce temporary dyspnœa. Patients are more or less emaciated, in proportion to the extent of their gastrectasia and to the nature of its cause. They are ordinarily anæmic, nervous, hypochondriacal, sleepless, and sometimes apathetic. They suffer from headache and nausea, perhaps referable to auto-infection with toxic ptomaïnes, and sometimes persisting for a number of days. The appetite is generally diminished, and often lost. If, however, there be no gastritis, the appetite may be good and even ravenous, because of the small amount of nourishment assimilated. There is often constant and tormenting thirst, only aggravated by the ingestion of liquids, because they augment the gastric dilatation and still further retard absorption. There is, ordinarily, a sensation of gastric oppression and distention, at least until the dilatation has progressed so far as to paralyze the gastric sensory nerves. This oppression is temporarily relieved by emesis. During the earlier stages of dilatation there is often acute gastralgia, probably due to advancing distention, and generally occurring after meals. This pain may be entirely relieved by the prompt and efficient use of the stomach-tube. Pyrosis and the eructation of badly smelling and tasting gases and liquids are frequent symptoms. True epileptic convulsions and tetanic spasms may occur in the latest stages of gastrectasia, as was first stated by Kussmaul. This author holds that they are due to abnormal dryness of the tissues from continuous abstraction of fluids, and are, hence, analogous to the convulsions in the asphyxia of cholera. Kussmaul supports this view by the fact that the spasms generally occur after emesis, or lavage of the stomach. It is, however, possible that the convulsions are due to cerebral and spinal anæmia, to toxæmia from the absorption of ptomaïnes, or to imperfect elimination of urea. The tetanic spasms involve by preference the abdominal muscles, the flexors of the hands and forearms, and the calves of the legs, but sometimes affect the muscles of the neck and face. The pupils are sometimes contracted, and nystagmus has been observed. Consciousness is commonly retained, but occasionally it is lost. Coma may follow the spasms or be developed independently of them. The convulsions may be momentary, or they may continue for hours or days. They are followed by great asthenia and by tenderness over the affected muscles. The spasms are not, in themselves, fatal.

Diagnosis.—Chronic gastritis may be mistaken for slight grades of gastrectasia, but may be differentiated by the application of the clinical test for dilatation already alluded to, *i.e.*, by ascertaining, with the syphon, whether the stomach habitually contains remnants of food in the morning, when the patient rises. If food be thus found, dilatation exists. *Ascites* may be mistaken for gastrectasia, but not if moderate caution be observed. In *hydroperitoneum*, flatness exists in the lowest abdominal regions when the patient is erect; the reverse obtains in gastrectasia. In simple hydroperitoneum there is no succussion sound. In hydroperitoneum the withdrawal of fluid from the stomach, by means of the tube, does not affect the size of the abdomen nor the area of dulness. *Hydatids of the liver*, ovarian tumors, distention of the urinary bladder, and pregnancy are said to have been mistaken for gastrectasia, but such errors need never occur, even to tyros in physical diagnosis.

Prognosis.—The best prognosis is afforded by cases of atonic dilatation without pyloric or duodenal obstruction. In these cases, if the dilatation be moderate in degree, a cure may be reasonably expected from proper treatment persistently pursued. In cases of marked atonic gastrectasia a complete cure is only rarely effected, and it must be admitted that the treatment is usually only palliative. Still, even in these cases, marked relief is often obtained, the patients gaining in weight and strength sufficiently to pursue their ordinary avocations for an indefinite period. A larger proportion of recoveries would, doubtless, be reported were it not for the fact that patients, encouraged by their notable improvement, and presuming too much upon their powers of digestion, frequently assign to the stomach tasks far beyond its capacity to perform, and wilfully violate fundamental dietetic laws. The prognosis, in dilatation secondary to obstructions which are not cancerous, is less favorable than that of

atonic gastrectasia, although life may be considerably prolonged and suffering be much relieved by proper therapeutic measures. In a few cases of cicatricial stenosis following ulcer, resection of the pylorus has permanently cured when all other means were unavailing. In dilatation from carcinomatous obstruction, the prognosis is hopeless. Gastrectasia, when fatal, usually causes death from inanition, very rarely by rupture of the stomach.

Treatment.—The treatment of gastrectasia embraces prophylactic and curative measures. The former are, in general, deplorably neglected, perhaps because the causes of dilatation are not fully understood. Prophylaxis is naturally powerless to avert certain obstructive lesions, such as carcinoma, but the timely and persistent treatment of subacute and chronic gastritis, as well as of asthenia and anæmia from various removable causes, might often avert atonic dilatation. It is the imperative duty of the physician to carefully follow cases of gastritis until the danger of gastrectasia is averted. Parents and guardians of the young should be made to understand the far-reaching and disastrous effects of overfeeding, and of disregarding so-called dyspeptic ailments of apparently trivial import. Young persons should be repeatedly warned against improper foods, immoderate indulgence and insufficient mastication. The curative treatment should aim to fulfil three indications: First, to empty and cleanse the stomach, and to prevent the recurrence of overdistention; second, to relieve coexistent gastritis; third, to improve the general condition of the patient. The objects accomplished by meeting these indications are the following: Thorough evacuation and cleansing of the stomach relieves tension of the gastric walls, placing them in a more favorable condition for regaining their normal resiliency and contractility. The peristole of the stomach is thus, in favorable cases, measurably strengthened, the secretion of the gastric juice restored, absorption facilitated and stagnation prevented. The removal of tenacious mucus and of irritating fermenting matters diminishes the dangers of auto-infection from ptomaïnes, checks morbid fermentations and subdues gastritis. The curative efficacy of these measures is most plainly manifest in moderate atonic dilatation, but even in incurable obstructive gastrectasia they are of inestimable value in palliating distressing symptoms. The relief of gastritis controls the hypersecretion of mucus, and aids the re-establishment of the normal gastric secretion, while improvement of the patient's general condition can but react favorably upon the local morbid conditions. In cases of moderate dilatation, particularly if the patients be women or children, heroic measures for the evacuation of the contents of the stomach are unnecessary. Mild cathartics, preferably hot salines, as Karlsbad salts, Hunyadi Janos, or citrate of magnesia, employed every second day, two hours before the morning meal, will usually suffice. In cases of marked gastrectasia, and in any instance where a speedy result of treatment is the first consideration, recourse should be had to the siphon-tube or to the stomach-pump. The medical world is indebted to Kussmaul for first advocating, in 1867, the systematic employment of these efficient means of emptying and cleansing the stomach. The instruments necessary for the mechanical cleansing of the stomach are, respectively, the ordinary stomach-pump, with its stiff gum-elastic tube, and a soft elastic stomach-tube, or catheter, to which a funnel is adapted, and which acts upon the principle of the siphon. The tubes generally employed in this country are made of perfectly elastic, reddish-brown rubber. Their diameter varies from one-fourth to one-half an inch, and their length from twenty-four to thirty inches. The writer prefers a tube about one-third of an inch in diameter. The so-called Faucher tube, much used in Europe, is six feet long, and the funnel is directly attached to its proximal extremity. The tube should always be new and strong, lest a portion be torn away and retained in the stomach, and it should be provided with two sunken, so-called velvet eyes, in order that the friction may be reduced to a minimum, and that one eye may remain pervious if its fellow becomes obstructed. The catheter proper is generally connected, by means of a small piece of stout glass tubing, with a piece of elastic tubing of about the same calibre as the catheter, which, when the tube is introduced into the stomach, constitutes the long arm of the siphon. The elastic tubing should be long enough to nearly reach the floor when the patient is seated. The use of the stomach-pump is so generally understood that any explanation is unnecessary. The pump should, in the writer's opinion, never be used when the soft tube will accomplish the object proposed, for the reason that its rigid tube is more disagreeable to the patient, and far more irritating to the œsophagus and the stomach than the elastic catheter. There is, moreover, danger that aspiration may be performed with such violence, by means of the pump, as to separate portions of the gastric mucous membrane. This accident has frequently occurred, and, although not serious, is still to be deprecated. In some instances better results are attained by the pump than by the soft tube. This is particularly true when a stomach containing large pieces of alimentary matter is to be cleansed. In such a case the eyes of the soft tube often become occluded by solid masses of food, and the aspirating power of the siphon is inadequate to their removal. The method of employing the siphon-tube is as follows: The patient should assume the sitting posture, throwing his head backward and holding his mouth open. The tube, having been lubricated with vaseline or oil, is introduced into the pharynx, and the patient is instructed to make repeated movements of deglutition. The physician may hasten the progress of the tube and prevent its rejection by making moderate pressure upon the proximal extremity. The tube, having been introduced to the depth of about twenty-six inches, is intrusted to an assistant, or to the patient himself, care being taken that it be held immovably in one position. This precaution is necessary, as movements of the tube often induce nausea and excite reversed œsophageal peristaltic movements. The funnel is now attached to the elastic tubing, filled with the liquid selected for irrigation, from a graduated glass, and elevated a short distance above the patient's head, as shown in Fig. 3733. In proportion as the liquid escapes from the funnel it is replenished, until about a pint has been allowed to flow into the stomach. Then, before all the liquid has escaped from the funnel, the latter is lowered to a point some feet below the stomach, as shown in Fig. 3734, and the contents of that organ evacuated by the action of the siphon. The elastic tube, to which the funnel is attached, should be longer than it is represented in the cut. It will be observed that the tube here shown is the long, continuous Faucher tube, often employed in Europe, but little used in the United States. When the current ceases to flow from the stomach, more liquid is introduced, and the process is continued until the liquid returns as clear as when

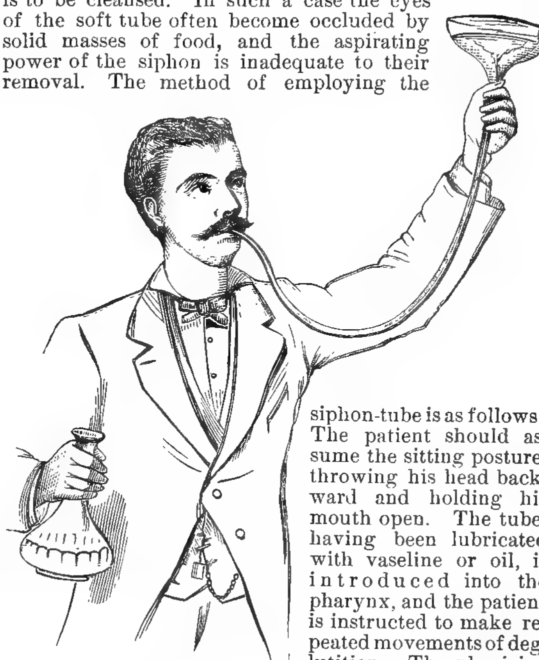

FIG. 3733.

it enters. The tube is then gently withdrawn, its upper end being compressed between the fingers to prevent the escape of the contained liquid. The liquid best adapted to the majority of cases is lukewarm water. Various medicaments may be added to the water to meet existing indications. If there be much acidity of the stomach from morbid processes of fermentation, one-half drachm of sodium bicarbonate may be added to each pint of water used. It is held by many that adhesive mucus is more easily detached by such an alkaline solution. If active fermentation is taking place in the stomach, antiseptics may be employed, the best being carbolic acid, salicylic acid and resorcin, in one per cent. solutions, these solutions being followed by a few measures of pure water. In cases characterized by great gastric irritability the writer has employed water at a temperature of about 102° F., with much success. The hot water appears to exert a decided sedative action upon the gastric mucous membrane, and to cleanse its surface more quickly and thoroughly than cool or lukewarm liquids. Certain difficulties may attend the simple operation of lavage. One of these relates to the introduction of the tube. This may be rendered very difficult by pharyngeal or œsophageal spasm. A certain amount of pharyngeal spasm generally occurs at the first introduction. This may often be obviated by spraying the throat, for a few minutes, with a two per cent. solution of hydrochlorate of cocaine. Should the spasm prove protracted, the operation may be postponed, or a tube sufficiently stiff to resist the muscular pressure may be introduced. After a few introductions this is usually unnecessary. Some patients complain of a sensation of oppression and of dyspnœa when the tube is in position. This discomfort is relieved by repeated deep inspirations, the air being allowed to enter through both mouth and nose. The current of liquid may be interrupted by various conditions. One of these is occlusion of the eyes of the catheter by food or mucus. The obstacle may sometimes be removed by voluntary straining efforts made by the patient, the breath being held and the abdominal muscles called into action, or by forced coughing. The obstruction may be temporarily removed by allowing more water to pass through the tube into the stomach, and the offending object will then occasionally present its shorter diameter to the eye and be expelled. Should all efforts at removing the obstruction fail, the tube may be removed, cleaned, and reintroduced, or, in the event of recurrent occlusion, the stomach-pump may be used. The current occasionally ceases because the tube has not been introduced to a sufficient depth and its eyes are above the level of the liquid contents of the stomach. On the other hand, the pliable tube, if introduced too deeply, may impinge upon the greater curvature of the stomach, or, passing into the pyloric region, may bend upon itself, thus checking the current. These difficulties are respectively obviated by withdrawing the tube or by introducing it to a greater depth. Paroxysms of coughing interrupt the current, the continuity of which is re-established by the introduction of more liquid. The liquid introduced should always be measured and compared with the amount withdrawn, in order that no accumulation shall take place. Cases have been reported by Jackson and Leube, in which the entire tube was swallowed and subsequently rejected by vomiting. This accident may be prevented by attaching a string to the upper extremity of the tube before its introduction. The leading contraindications to the use of the tube are aneurism of the aorta, recent gastrorrhagia, most cases of gastric ulcer, cancer of the œsophagus or of the cardiac orifice and marked asthenia. The passage of the tube sometimes produces such violent vomiting and œsophageal spasm as to cause syncope, in which case the simpler methods of cleansing the stomach must be relied on. Authorities do not agree regarding the best time of day for the operation of lavage. The majority are, however, in favor of performing the operation before breakfast. The writer prefers this time, because the stomach has then had the fullest possible opportunity for the digestion and absorption of food. Less chyme is thus lost than when lavage is done later in the day. Again, the food, having been reduced to a pultaceous mass, does not obstruct the tube, and the operation is thus accomplished with greater certainty and despatch. The stomach should be washed every day at the beginning of the treatment. Later, if progress be satisfactory, it may be washed every second or third day. The frequency of the operation is, however, to be entirely governed by the symptoms in each case. The use of the soft tube may be safely left to the patient, after a few lessons. The use of the tube should not be continued after the stomach is restored to health, and patients should be cautioned not to allow the consciousness that relief from suffering can be quickly obtained by a resort to the tube to betray them into dietetic indiscretions.

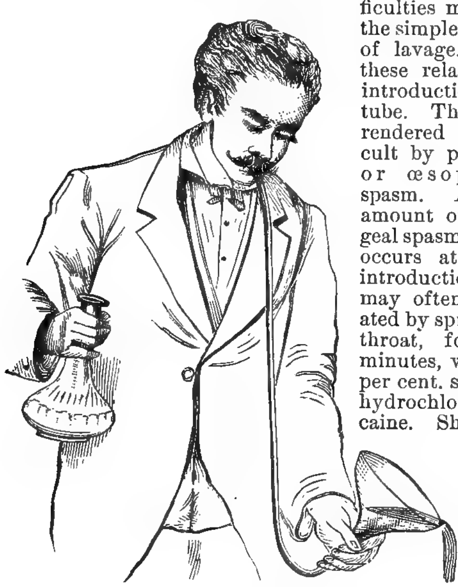

FIG. 3734.

The dietetic treatment of gastrectasia is even more important than the mechanical. The objects to be accomplished by regulation of the diet are the prevention of fermentation, of overdistention and of irritation. The foods selected should, therefore, be mostly solid, small in volume, unstimulating, not easily fermentable and not hot. They should be taken at intervals of two or three hours, in small quantities. Liquids should be taken sparingly, thirst being relieved by small swallows of water, rather than by large volumes taken at one time. Nitrogenous foods are, in general, preferable to the carbo-hydrates and fats, because the former are small in bulk, and since the latter, not being acted on by the gastric juice, tend to more rapid decomposition and fermentation. According to this principle, fresh mutton and beef, eggs, oysters and tender chicken are ordinarily best tolerated, tender cold mutton usually proving the most digestible of all these foods. Toasted bread, with a little fresh butter, may soon be added to the *menu*, and weak tea, or weak *percolated* coffee, without sugar, may be sparingly used with the meals. If the case progresses favorably, other vegetable foods may be tentatively added to the bill of fare, and baked apples, with sweet cream, may be used as a dessert. All spices and condiments, save a moderate quantity of salt, and all alcoholic beverages, are to be rigidly withheld, unless at times of great exposure or of marked exhaustion, when pure whiskey, well diluted, may be sparingly taken. Opium, cocaine, and other drugs which diminish gastric peristole, are to be forbidden, unless required to meet special indications. In the first days of the treatment the writer has often successfully employed a diet composed exclusively of predigested aliment, in the form of peptonised milk. A large part of the milk, being quickly transformed into peptones, is absorbed, and the objection usually urged against fluid foods—namely, their large bulk—is thus removed. When this plan is adopted, two or three quarts of peptonised milk are given daily, in divided doses, the intervals of drinking being from two to three hours. Leube-Rosenthal's beef solution and the so-called beef peptonoids of Rudisch are often of great value when milk

in any form is not well borne. When hardly any food is absorbed from the stomach, as in advanced hypertrophic gastrectasia, rectal alimentation may prolong life for some time. The *medicinal treatment* of gastric dilatation is not complicated. Digestion may be materially assisted by the judicious use of pepsin and dilute hydrochloric acid, given an hour after meals. Three grains of pepsin and five drops of the acid are fair average doses. The acid should be well diluted and gradually sipped, rather than taken all at once, if the patient's time will allow. Nux vomica or strychnine may be used if a tonic is indicated, and, aside from meeting this indication, it may render some service in increasing the contractility of the gastric muscles. Faradic electricity is also useful for the same purpose. It may be employed every day for five or ten minutes, both poles being applied to the epigastrium, or one pole to that region and the other to the lower dorsal region of the spine. If there be notable gastric acidity, with eructations, bicarbonate of sodium should be taken in twenty-grain doses, with water, ten minutes before meals. Constipation may be relieved by laxative enemata, or by a pill containing aloin, belladonna and strychnine. Ergotin, hypodermatically administered, has been recommended to stimulate gastric peristole, and an abdominal bandage, if not uncomfortably tight, may be useful in supporting the distended stomach. Abdominal massage improves the tone of the gastric and of the intestinal muscles. The constitutional condition of the patient claims attention. It will generally improve *pari passu* with the stomach. Mild preparations of iron, such as the carbonate, if well tolerated, may be used for anæmia. Patients should guard themselves against exposure, since their vitality is lowered and their powers of resistance impaired. They should be urged to exercise moderately in the open air, always within the bounds of slight fatigue, and should sleep seven or eight hours at night in well-ventilated rooms, resting, as much as possible, upon the right side. This position favors the emptying of the stomach, by allowing the contents of the organ to gravitate toward the pylorus.

Acute Dilatation of the Stomach.—This term has been applied to rapid overdistention of the stomach; supposed to be due to sudden paralysis of the gastric muscles and the consequent retention of all fluids and solids introduced into the stomach. The chief causes to which the overdistention has been referred are abdominal injuries, acute gastritis, acute peritonitis, fevers and boulimia. It is not certain that true paralysis of the stomach exists in these cases, nor has it been proved that chronic gastrectasia has not preceded the development of supposed acute dilatation. The symptoms usually stated to be characteristic of sudden overdistention of the stomach are severe gastric pain, gastric tympanites, cerebral anæmia, and the absence of emesis, or its cessation if it existed before the occurrence of acute overdistention of the stomach. The treatment of overdistention, whether suddenly or slowly developed, embraces lavage, as described in the section on gastrectasia, the use of foods both small in bulk and easily digestible, the employment of pepsin and of hydrochloric acid and the adoption of measures calculated to restore vigor to the atonic stomach.

Ulcer of the Stomach.—*Synonyms:* Perforating, chronic, round, peptic or digestive, eroding and simple gastric ulcer. The terms perforating, chronic, and round are not always appropriate, as many ulcers do not possess the characteristics described by these adjectives.

Frequency.—Gastric ulcer occurs very frequently, and, according to many authorities, is found, either open or cicatrized, in five per cent. of all autopsies.

Etiology.—Women between the ages of twenty and thirty are particularly liable to ulcer, and, in general, females are more often attacked than males, the proportion being, according to Brinton, as three to two. Men between thirty and forty are more liable to the disease than at other ages, while children are rarely affected. Ulcer is more common in anæmic, chlorotic, and enfeebled subjects than in strong and plethoric persons, and is more frequent in England and France than in the United States. Occupations which engender irritation of the stomach may predispose to gastric ulcer. Thus, cooks and knife-grinders, who swallow irritating substances, are said to lend a large contingent to the victims of the disease. Injuries of various kinds may constitute predisposing or exciting causes of ulcer, as will be explained under the heading *Pathogenesis.* Ulcers due to traumatism possess, as was shown by the experiments of Cohnheim, an unexplained tendency to ready healing, which does not belong to ulcers from other causes.

Pathogenesis.—Nearly all authors agree in regarding gastric ulcer as resulting from localized auto-digestion of the stomach-walls, and refer this auto-digestion to impaired circulation and nutrition in those areas which are the seats of the ulcerative processes. There are many divergent views regarding the nature and cause of the circulatory disturbance in the gastric vessels which is assumed to produce ulceration. Virchow holds embolism or thrombosis of the gastric arteries responsible for the vascular disturbances, but his view is not supported by anatomical evidence, as has been shown by Cohnheim, who, however, together with Panum, produced gastric hæmorrhagic infarction and ulcers, in dogs, by artificial embolic occlusion of the small gastric arteries. Klebs believes local spastic contraction of the arterioles to be the causative vascular condition. Other writers attribute the assumed circulatory disturbances to diseases of the gastric arteries, such as amyloid, fatty and atheromatous degenerations, to venous thrombosis, to vaso-motor neurosis and to excessive acidity of the gastric juice. Rindfleisch advanced the theory that the chief vascular disturbance leading to ulceration was generally hæmorrhagic infarction or venous hæmorrhage, the ulcer being produced, according to this theory, in essentially the same way as hæmorrhagic erosions. Rindfleisch's view, which has met with general favor, is supported by the experiments of L. Müller, who produced gastric hæmorrhages, hæmorrhagic erosions and ulcers, in rabbits, by obstructing the portal vein and the larger gastric veins. Various conditions may lead to the venous hæmorrhages supposed by Rindfleisch to cause ulcer, chief among them being spasm of the gastric muscles, by which the thin-walled veins are compressed and overdistended (Axel Key), varicose veins, passive congestion, and injuries, whether mechanical, chemical, or thermal. The nature of the changes in the mucous membrane dependent upon the above-named disturbances of the circulation, by which the membrane is rendered vulnerable to the attacks of the gastric juice, has also been the subject of long controversy. Pavy first formulated the theory that auto-digestion was prevented, during life, by the alkalinity of the blood coursing through the vessels of the gastric mucous membrane, by which the acid gastric juice was neutralized. In accordance with this view, impairment of the circulation would diminish the supply of alkaline blood, and the gastric juice would then be free to act upon the defenceless tissues. Pavy's theory is widely accepted, although not susceptible of absolute demonstration. It is, however, quite possible that some unknown vital property of the healthy gastric mucous membrane prevents auto-digestion, rather than the alkalinity of its contained blood, and that the loss of this property, from impairment of the circulation, facilitates the action of the gastric juice upon the enfeebled gastric tissues.

Pathological Anatomy.—Peptic ulcers are produced and extended by non-inflammatory, molecular necrosis, which, beginning in the mucous membrane, may involve only this and the submucosa, or may erode all the coats of the stomach. Peptic ulcers are situated in those parts of the digestive tract which are accessible to the gastric juice. Their favorite seat is in the pyloric region of the stomach, on the posterior wall, at or near the lesser curvature. Less frequently ulcers are seated in other regions, on the anterior wall, or at the greater curvature. They have been often found in the cardiac extremity and, rarely, in the œsophagus and in the duodenum. Welch analyzed a series of 793 gastric ulcers with reference to their seat, and found the ulcer at the lesser curvature in 288 cases,

on the posterior wall in 235, at the pylorus in 95, on the anterior wall in 69, at the cardiac orifice in 50, at the fundus in 29, and at the greater curvature in 27 cases. Usually there is but *one* ulcer, but two or more ulcers are found, according to Brinton's statistics, in twenty-one per cent. of all cases. The size of the ulcer varies from that of a pin-prick to a diameter of several inches. Delafield and Prudden give six inches as the maximum size. Cruveilhier described an ulcer six and one-half inches in length and three and one-half inches in breadth. The average size is that of a quarter of a dollar. The shape of the ulcer is commonly round, oval, or elongated, rarely annular, sometimes irregular, from the coalescence of neighboring ulcers. The loss of substance in the mucous membrane is ordinarily greater than in the deeper gastric tissues, so that a typical ulcer is of a peculiar funnel-shape, which is not, however, constant, particularly in old ulcers. The aperture in the mucous membrane is sharply defined in recent ulcers, as if a portion of the membrane had been removed by a punch. The various deeper layers can sometimes be distinguished by the varying extent to which they are eroded. Occasionally, however, the walls of the ulcer are both vertical, instead of being sloping, and sometimes they are swollen and infiltrated with blood. Virchow states that the most characteristic arrangement of the ulcer's walls consists in one side being vertical and the other sloping or terrace-like. Orth called attention to the direction of the axis of the ulcer, which is often not perpendicular to the mucous surface, but obliquely directed, as are the gastric arteries. The base of the ulcer is composed of one or the other coat of the stomach, unless complete perforation has occurred. In this case the base may be formed by the liver, by the pancreas, or by some other organ. The base of recent ulcers may be smooth and firm, soft, irregular, or hæmorrhagic, generally presenting no pus and being devoid of granulations. In old ulcers the base is often anæmic, even, and indurated, the edges being hard and elevated, from the development of new connective tissue. The tissues in immediate proximity to recent ulcers contain granular detritus, composed largely of amorphous remnants of connective-tissue fibres, of disintegrated red blood-corpuscles and of fatty granules. The tubules are often compressed and separated from each other by this granular matter. Some of the blood-vessels contain thrombi. Around the margins of the granular detritus is occasionally found a band of tissue infiltrated with lymphoid cells. The blood-vessels in the newly developed connective tissue have their walls thickened by endarteritis or by atheroma. They sometimes contain thrombi. The new tissue may develop in the mucous membrane, around the ulcer for a considerable distance, compressing or obliterating the gastric tubules, and causing inflammation and atrophy of the nerve-filaments. The ulcer frequently erodes blood-vessels in its wall or on its base, causing hæmorrhages which, according to the size of the vessels, may be trivial, dangerous, or even fatal. Serious hæmorrhages occur in only about one-third of the cases, and generally proceed from the splenic, the pyloric, the coronary, the gastro-epiploic, or the gastro-duodenalis vessels. Sometimes, however, grave hæmorrhage may come from erosion of the hepatic, pancreatic and mesenteric arteries and veins, or from varicose gastric veins. Peptic ulcers often heal spontaneously, leaving a cicatrix which is ordinarily stellate, and which often, in contracting, produces deformities of the organ or obstruction of the pylorus. In the former case the stomach may be divided into two unequal parts, and in the latter gastrectasia may result from the obstruction. Ulcers may coexist with cancer, and are often complicated by chronic gastritis. If an ulcer perforates all the layers of the gastric parietes, which occurs most frequently when the ulcer is situated on the anterior wall, the contents of the stomach may escape into the peritoneal cavity, producing rapidly fatal peritonitis; or if the perforation takes place slowly, local peritonitis is developed, and causes adhesions between the stomach and other organs which then form the floor of the ulcer. Under these circumstances the process of ulceration may invade these organs, especially the liver, producing irregular cavities and, occasionally, abscesses. The pancreas is not often deeply eroded. The ulcer may open into the pleura, the large or small intestine, the mediastinum, the pericardium, the left ventricle, the left bronchus, the common bile-duct, the pancreatic duct, the gall-bladder, the lung, on the surface, or into the portal vein. When perforation of this vein occurs, pylephlebitis is commonly the result. When the stomach communicates with the cavities of hollow viscera, or with the cutaneous surface, the channels of communication are called gastric fistulæ. Typhoid and tuberculous ulcers are rarely found in the stomach, but cases have been recorded in which they caused perforation and hæmatemesis. Necrotic gastric ulcers also sometimes occur in diphtheria, pyæmia and phlegmonous gastritis.

Clinical History.—In many cases gastric ulcers remain entirely latent throughout their course, as is proved by the post-mortem discovery of open or of healed ulcers in patients who have never presented any symptoms of the disease and have died of other complaints. Less frequently there are no symptoms until perforation suddenly occurs and induces fatal peritonitis or shock. In still another class of cases there are distinct symptoms, which are, however, not peculiar to ulcer, such as vomiting, eructations, anorexia and pyrosis. Generally, however, certain diagnostic symptoms are present, the leading ones being pain, localized tenderness and hæmatemesis. Pain is the most constant symptom of ulcer. The pain may be either continuous or intermittent, dull and gnawing, or lancinating, confined to one spot or radiating into various organs and members. The diffuse pains are not characteristic of ulcer, as they may be excited by gastritis or by various other causes. The kind of pain which, when present, is most characteristic of ulcer is circumscribed, gnawing or boring, generally epigastric or dorsal, or both, appearing soon after the ingestion of food, and generally ceasing when the food has been expelled into the duodenum or has been rejected by vomiting. This pain is therefore probably due to the chemical and mechanical irritation of the food and of the gastric juice. It is usually intensified by stimulating articles of diet, and by fermentations producing abnormal acids in the stomach, being lessened by bland aliments and by the neutralization of the abnormal acids with alkalies. When, as occasionally happens, the circumscribed pain persists after the expulsion of the gastric contents, it is probably due to localized peritonitis, to abscesses in neighboring organs or, in some cases, to an abnormal secretion of hydrochloric acid. The pain may sometimes be modified by position, the dorsal decubitus commonly affording relief when the ulcer is on the anterior gastric wall, and the prone position when the ulcer is located posteriorly. Pressure ordinarily increases, but, rarely, mitigates the pain. It is to be borne in mind that this pain may sometimes be entirely absent in cases of gastric ulcer. Circumscribed tenderness on pressure, corresponding to the seat of the ulcer, is a valuable and quite constant symptom. Pressure should, however, be carefully employed, as it has been known to cause perforation. Vomiting is another cardinal and fairly constant symptom, varying greatly, however, as to frequency, in different cases. Vomiting may be due to coexisting gastritis or to irritation by the ulcer. It may occur after cicatrization of an ulcer, from irritation of the stomach or from obstructive gastrectasia. Sometimes it occurs several times daily, and sometimes only once or twice a week. When present, emesis usually takes place soon after the ingestion of food, particularly if the latter be hot or possess irritating mechanical and chemical properties, and is preceded by pain. Occasionally vomiting occurs independently of eating and without premonitory discomfort. The act of emesis, although generally not violent, results in the complete evacuation of the gastric contents and in the relief or marked alleviation of the pain. The vomited matter contains portions of food, mucus, bacteria, sarcinæ, occasionally bile and sometimes blood. Hæmatemesis occurs in about twenty-five per cent. of all cases. This percentage does not accurately represent the frequency of gastrorrhagia, be-

cause slight hæmorrhages often occasion no vomiting, and the blood, being digested, does not appear in the dejections. Even when large hæmorrhages occur, there may be no vomiting, but merely more or less marked melæna. If hæmatemesis occurs after a moderate gastrorrhagia, the blood is generally acid, coagulated, and resembles coffee-grounds or tar. This appearance is due to the action of the gastric juice upon the coloring matter of the red corpuscles and upon the proteids of the plasma. If the hæmorrhage be very profuse, the vomited blood may be arterial in color, uncoagulated and of alkaline reaction. Several pints of such blood may be rejected at once. In about four per cent. of all cases the hæmorrhage is sufficiently profuse to induce fatal collapse. In such cases all the blood may, sometimes, be retained in the stomach, or only a small part of it may be vomited. The gross appearance of vomited matters which contain blood is ordinarily quite characteristic. In cases of doubt, the microscope or the spectroscope may be called into requisition. After hæmatemesis melæna may persist for several days. Perforation of the ulcer into the peritoneal cavity occurs in about six and a half per cent. of all cases, and is generally rapidly fatal either from shock or from acute peritonitis. Perforation is, in certain rare cases, the first and only symptom of an ulcer. Perforation occurs most frequently in females between the ages of fifteen and thirty years, the proportion of cases occurring in females and males being, respectively, as three to one. Ulcers on the anterior wall of the stomach cause perforation more frequently than those in other locations. When gases escape from a perforated stomach the liver, unless adherent, may be pressed backward and the normal hepatic flatness replaced by tympanitic resonance. If the perforation is small, it may cause localized peritonitis with adhesions to, and abscesses in, the various organs invaded, and generally proves lethal by exhaustion. In this way sub-diaphragmatic abscesses, simulating pneumo-pyothorax, may occur, or, adhesions between the stomach, the diaphragm and the pleura having taken place, the pleura and lung may be perforated and pulmonary abscess and gangrene excited, or pleuritis and pneumo-pyothorax induced. If the perforation occurs into the colon, fæces may be vomited. Rarely, the pericardium is invaded, and pericarditis results, or the portal vein is penetrated, and pylephlebitis with pyæmia follows. Perforation is usually caused by some sudden exertion, as lifting, coughing and vomiting, or by overdistention of the stomach with gas or food. The general symptoms in progressive ulcers are chiefly those of indigestion and the consequent malnutrition. The patients lose weight and strength, and, if hæmorrhage occurs, become more or less anæmic and œdematous. After large hæmorrhages this anæmia may become acute. The symptoms of chronic gastritis are commonly present. The bowels are ordinarily constipated and amenorrhœa is frequent. In some cases, however, there is hardly any interference with the general condition, and even the presence of large ulcers may not be incompatible with fairly good health. The cicatrization of ulcers may cause gastralgia, from traction upon the peritoneum, or it may lead to gastrectasia. Relapses, after apparent recovery from ulcer, are not rare.

Diagnosis.—Many gastric ulcers, presenting no diagnostic symptoms, necessarily escape observation. None of the cardinal symptoms of ulcer is absolutely pathognomonic, but, when associated, they usually render the diagnosis sufficiently clear to justify the adoption of measures adapted to the cure of ulcers. The characteristic features of the pain of ulcer are its localization, its aggravation by eating and by pressure, and its relief by evacuation of the stomach and by changes of posture. Hæmatemesis is the most important symptom of ulcer, and in young people should always excite suspicion of its existence.

The *differential diagnosis* lies between ulcer, gastralgia, chronic gastritis, cancer, hæmatemesis without ulcer and so-called biliary colic.

Gastralgia is not accompanied by tenderness, being rather relieved by pressure, and is paroxysmal, while the pain of ulcer is often continuous, and is aggravated by pressure. Eating does not usually excite simple gastralgia, but mitigates it. Vomiting is not so constant in simple gastralgia as in ulcer, and does not relieve the pain.

Hæmatemesis is not a symptom of gastralgia. The general health is often but little impaired in gastralgia, which often coexists with neuralgias in other organs. Chronic gastritis may be confounded with ulcer and, indeed, generally complicates the latter. Existing alone, it may even have all the cardinal symptoms of ulcer, but to a less degree. Thus, hæmatemesis is more rare, vomiting less common, and the pain less severe, more disseminated, and not paroxysmal. The results of treatment are less marked and speedy in chronic gastritis than in ulcer. The differential points between ulcer and cancer will be found in the remarks upon the diagnosis of cancer in the section on that subject. Hæmatemesis from various causes other than ulcer is to be excluded by careful attention to the history of each case (*vide* article Hæmatemesis in this HANDBOOK). So-called biliary colic, from the passage of biliary calculi, has some symptoms in common with ulcer, but the pain is situated in the right hypochondrium, and sometimes radiates to the right shoulder. The pain begins and ends abruptly, without reference to the ingestion of food. There is no epigastric tenderness. Jaundice is usually present. Biliary calculi are sometimes found in the dejections, after an attack. Sometimes the liver and the gall-bladder are enlarged in cases of biliary colic.

Prognosis.—It is estimated that about fifteen per cent. of all gastric ulcers end in recovery by cicatrization, the prospect for this desirable termination being good in proportion as the ulcer is superficial and recent, the patient's general condition good, and the treatment judicious. The causes of death are chiefly perforation, which ends fatally, according to Welch, in about six and a half per cent. of all cases; hæmorrhage, which is fatal in about four per cent. of all cases; and inanition, which is mainly responsible for the high average rate of mortality. Perforation, which is most common with ulcers on the anterior wall of the stomach, causes death by shock, by general peritonitis, or by localized inflammations. Yet some cases of slight perforation recover by the gradual subsidence of the resulting inflammatory complications, or by evacuation of abscesses. A profuse hæmorrhage is of bad prognostic import, betokening deep ulceration and causing anæmia, which itself predisposes to the development of new ulcers. Continuous pain, irrespective of the introduction of food, is an unfavorable symptom, pointing, together with a rise of temperature, to extra-gastric inflammation. Ulcers may be indirectly fatal even after their cicatrization, by causing gastrectasia, sacculation of the stomach, or, very rarely, rupture at the seat of the cicatrix. The duration of the disease is most uncertain, varying from a few days to many years. Brinton reports a case in which the ulcer continued open for thirty-five years, and several cases the duration of which was thirty, twenty, and fifteen years, respectively. The prognosis for a cure of old ulcers is naturally less favorable than for recent ones, since the fibroid thickening in the borders of the ulcers retards the progress of cicatrization. Relapses, after apparent complete cicatrization, are quite common, and carcinoma may develop from the floor of the cicatrix.

Treatment.—Whenever the symptoms are such as to render the existence of gastric ulcer even probable, appropriate treatment should be at once begun and persistently carried out. The objects of the treatment are to secure as absolute rest as is possible for the stomach, to prevent all chemical and mechanical irritation of the ulcer, to relieve pain, to prevent vomiting, and to check hæmorrhage, if these symptoms exist, to sustain the patient's strength, and to overcome his anæmia. The first two indications are best fulfilled by keeping the patient in bed, in that position which gives him the greatest comfort, and by withholding all food from the stomach. In some recent cases, the patients possessing a fair amount of strength, rectal alimentation may be exclusively employed for some weeks, and, in every case, it is desirable that no food be taken by mouth for at least several days.

Persistent vomiting and gastrorrhagia, at any period of the treatment, also naturally constitute urgent indications for rectal alimentation. The methods of preparing and of using nourishing rectal enemata, in cases of ulcer, are the same as those described under the treatment of gastritis, to which the reader is referred. The best materials for alimentary injections are Leube-Rosenthal's beef solution, Rudisch's beef peptonoids and peptonised milk. The last is prepared by means of Fairchild and Foster's peptonising tubes, to be obtained of any druggist. The quantity of these substances which the rectum will tolerate, and the length of the intervals between the enemata, can be best ascertained by trial. In general, from four to six ounces of fluid may be injected every three or four hours, a simple cleansing enema being also daily employed, and a few drops of the tincture of opium being added to each nutritive enema, for the purpose of obtunding the sensibility of the rectum and facilitating the retention of the enema. It would be advantageous to continue rectal alimentation until the evidences of complete cicatrization were obtained. In practice, however, this method is often objectionable, on account of aversion on the patient's part, and because it does not adequately sustain the vital forces. So soon, therefore, as these obstacles are encountered, rectal alimentation is to be supplemented or superseded by stomach-alimentation, unless pain and hæmorrhage absolutely contra-indicate feeding by the mouth. The foods recommended for rectal injection are also the best for use under these circumstances, and the writer gives the preference to peptonised milk. The food selected should be taken at intervals of two or three hours, and in small quantities. Urgent thirst may be quenched by cracked ice, in small pieces, dissolved slowly in the mouth. If none of the above-named foods be obtainable, sweet milk is the next best article of diet. Of this about two quarts should be given daily, and no other aliment employed for at least two weeks, unless there be considerable loss of weight and strength. Should emesis and pain return under this regimen, recourse must again be had to rectal alimentation. At the end of two weeks, or sooner, if the general condition of the patient demand more nourishment and there be no contra-indications, other articles of food may be experimentally employed. The qualities most desirable in these foods are blandness, concentration, softness and freedom from a tendency to fermentation. At first, raw eggs may be added to the milk and taken soft-boiled or poached ; then well-toasted bread, soaked in the milk, thoroughly boiled rice, or soda biscuits. Should a diet strictly limited to these articles be well borne, rare beefsteak, finely scraped, tender mutton-chop, thoroughly minced, stewed sweetbreads, cold roast mutton, raw or slightly cooked oysters, and the breast of chicken may be alternately used, in small quantities. Baked potatoes with fresh butter, cornstarch, sago, and tapioca cooked with eggs and milk, may also be allowed. All cooked fats, strong acids, spices and condiments, cheese, pickles, pastry, coarse and irritating foods such as cabbage and oatmeal, liquors, wines, and fruits, are to be carefully avoided. Violent exercise should not be taken. All these foods should be taken moderately warm, and should be *exclusively* used until cicatrization is believed to be complete, when the patient may gradually add any easily digestible foods to his *menu*. He should, however, ever after his attack, rigidly exclude all coarse, irritating, and indigestible aliments from his diet. A relapse should be the signal for an immediate return to the simplest foods or to rectal alimentation. Comparatively little can be accomplished by medicinal agents for the cure of ulcer. Great benefit is, however, often derived from the use of antacid remedies for the relief of pain due to the presence of abnormal acids, or of excessively acid gastric juice. The bicarbonate of soda fulfils this indication admirably when given in twenty-grain doses, before eating, or whenever the pain is felt. Bismuth subnitrate, in one-half-drachm doses, has rendered good services in some of the writer's cases, and seems especially beneficial in cases of ulcer complicated with chronic gastritis. These cases are most easily amenable to *lavage*, which, cautiously performed with the soft tube, can hardly do harm unless contra-indicated by great gastric irritability or by hæmatemesis. If lavage be employed, only about eight ounces of water should be slowly introduced at one time, and at once withdrawn, care being taken to secure the return of all the liquid. Ziemssen advocates the use of Carlsbad salts for the relief of the gastritis complicating ulcer. One or two drachms of the salts are to be dissolved in one-half pint or a whole pint of water at a temperature of 95° F., and one-fourth of this solution is to be drunk at intervals of ten minutes, the last dose being taken one hour before breakfast. Should the above quantity of salts not produce a loose movement after two or three hours, the quantity should be cautiously increased on the following days, until the desired result is obtained. Laxative enemata and the use of the soft tube are, perhaps, better adapted to cases of severe chronic gastritis, while the salts do well in milder cases. The pain of ulcer is best controlled by careful regulation of the diet and the use of alkalies according to the rules already given, or by temporary rectal alimentation. Gastralgia may be so severe as to require opiates, best given hypodermatically or by the rectum, which must, however, be withdrawn so soon as practicable, lest the opium-habit be engendered. Counter-irritation of the epigastrium is also useful. If constant pain, with fever, points to perigastritis or to local peritonitis, ice-bags may be applied. Vomiting is, likewise, most easily subdued by rest, mild diet, or, failing these, by rectal alimentation and opiates.

Hæmatemesis calls for rectal alimentation, rest, ice-bags to the epigastrium, and ergotin in solution, by the rectum or hypodermatically. For hypodermic use the following solution is appropriate :

℞. Ergotin, vel Squibb's ext. ergotæ. .. gr. xlviii.
Aquæ,
Glycerinæ...................... āā fl ℥ j.
M. Sig.—♏. 20 = gr. j.

Twenty minims of this solution may be injected several times, at intervals of a few hours. Twice the quantity may be given in warm water, at the same intervals, by the rectum. Morphine, hypodermatically administered, is also indicated. If the hæmorrhage be so profuse as to cause dangerous cerebral anæmia, brandy and ether may be given subcutaneously, ammonia inhaled, and transfusion performed. In the event of perforation, rectal alimentation, morphine, and warm fomentations are indicated, and, although not curative, serve to mitigate suffering and thus to promote euthanasia. Rydygier recommends laparotomy for perforation, and closing the ulcer with sutures. The same operator and Van Kleef and Czerny each successfully performed extirpation of a cicatrix which was producing pyloric stenosis and gastrectasia. Most physicians will, however, be content to treat gastrectasia by the method recommended in the section on that subject. The chronic anæmia resulting from ulcer is to be met with mild ferruginous preparations, well diluted, which should, however, be withheld until after complete cicatrization of the ulcer.

CANCER OF THE STOMACH. *Pathogenesis.*—Nothing is definitely known about the essential cause of cancer in general, and this statement of course applies with equal force to the origin of gastric carcinoma. Virchow advanced the theory that cancer results from long-continued normal or pathological irritation, and adduced the fact that the orifices of the stomach which are subjected to the greatest amount of friction are most frequently attacked, in support of his doctrine. Cohnheim's theory refers the origin of carcinoma to abnormalities in cellular development, and particularly to the persistence of embryonic cells. In accordance with this theory, pyloric cancer is most common on account of the complex development of that part of the stomach.

Frequency.—The stomach is, after the uterus, the most frequent seat of primary cancer. Many authors place gastric carcinoma first in point of frequency, but the carefully collated statistics of Welch show that one-third of all primary cancers are uterine and one-fifth gastric. According to Virchow, 34.9 per cent. of all cancers are

gastric, and 1.9 per cent. of deaths from all causes are due to this disease.

Etiology.—No occupation, injury, previous general disease, or mental condition has any etiological relation to gastric cancer. Age exerts a well-recognized causative influence. Three-fourths of all the cases occur between the ages of forty and seventy years, the largest number taking place between the ages of fifty and sixty. Gastric carcinoma is exceedingly rare in childhood, and infrequent after the seventieth year. Lebert concludes that hardly one per cent. of the cases occur before the thirtieth year, 16.3 per cent. between the sixtieth and the seventieth year, and 4.4 per cent. after the seventieth year. The cases are about equally distributed between the sexes, males being apparently rather more frequently attacked than females. Heredity exerts a causative influence. Welch states that in about fourteen per cent. of all cases it can be ascertained that relatives of the patient have suffered from the disease. Gastric cancer occasionally develops from a gastric ulcer, either open or cicatrized, which fact is of considerable practical importance. Cancer is said by Griesinger to be unknown in Egypt, and is also said to be rare in other tropical countries.

Morbid Anatomy.—A gastric cancer is most commonly situated at or near the pylorus, and generally on the posterior surface or at the lesser curvature. Welch analyzed 1,300 cases, with reference to the situation of the tumors, with the following results: Pyloric region, 60.8 per cent.; lesser curvature, 11.4 per cent.; cardiac extremity, 8 per cent.; posterior wall, 5.2 per cent.; the whole or the greater part of the stomach, 4.7 per cent.; multiple tumors, 3.5 per cent.; greater curvature, 2.6 per cent.; fundus, 1.5 per cent. Gastric carcinomata are usually primary, very rarely secondary. The varieties of gastric cancer are the cylindrical-celled, the scirrhous, the medullary and the colloid or alveolar. Combinations of these varieties often occur. Colloid cancer is the least common, and the cylindrical-celled the most frequent variety. The alveoli of cylindrical-celled carcinomata resemble the structure and arrangement of normal gastric tubules, the cells lining the alveoli being of cylindrical form. The consistency of this variety of cancer is soft. Scirrhous cancer is largely composed of a fibrous stroma, the alveoli being comparatively small. Scirrhus may be either nodular or diffuse, grows rather slowly, and does not so readily ulcerate as the other forms of cancer. Medullary cancer grows rapidly and readily occasions metastases. Its alveolar structure predominates quantitatively over the fibrous stroma, and it is consequently soft. It grows rapidly and ulcerates readily. Colloid cancer is either nodular, infiltrated, or annular. It is soft, the alveoli containing a clear, jelly-like substance, but it does not so readily ulcerate as the other varieties of carcinoma. According to Waldeyer, the origin of gastric cancer is in the mucous membrane, whence it extends to the submucosa and to the other tunics of the stomach. Sometimes the neoplasm is apparently seated in the submucosa, but careful search will show the tubules to be involved, connecting bands extending between these and the submucosa.

Ulceration occurs in three-fifths of all cases; most frequently, according to Lebert, in medullary, and least frequently in colloid, cancers. The ulcers vary in size, may be irregular or crater-like in form, and often show eroded or obstructed vessels in their base. Partial cicatrization of the ulcers sometimes occurs. Ulceration may reduce the size of cancerous tumors, and thus prevent or remove pyloric stenosis. If stenosis of the pylorus persist, gastrectasia ensues. Chronic gastritis usually accompanies carcinoma. Sometimes cancer causes atrophy of the stomach by obstructing its cardiac orifice. Progressive carcinomatous ulceration may perforate the stomach, causing hæmorrhage from erosion of the vessels, chronic adhesive peritonitis, or, more rarely, diffuse peritonitis. Violent gastrorrhagia and peritonitis from perforation are, however, less common with cancer than with ulcer. The ulcer may invade the pancreas, the liver, the diaphragm, the pleura, the pericardium, the spleen, etc., or it may establish fistulous communications between the stomach and the pleural, the peritoneal, or the pericardial cavities, and with the colon. Gastric cancer may also extend by metastasis through the lymphatics or the blood-vessels. The secondary growths are usually identical in structure with the primary neoplasm. The lymphatic glands near the stomach constitute the most frequent site of metastatic deposits, and next to these the liver, the peritoneum, the pancreas and the lungs, in the order named.

Clinical History.—As in gastric ulcer, so in cancer, particularly if it be secondary, there are sometimes no symptoms, death being due to intercurrent diseases. This rarely occurs, but shows that the duration of carcinoma cannot always be accurately estimated from the first unmistakable symptoms. In other instances local symptoms and signs referable to the stomach are trifling or absent, while emaciation, anæmia, and exhaustion are rapidly progressive. These cases are sometimes mistaken for phthisis, for Bright's disease, or for pernicious anæmia. In typical cases, however, there are symptoms and signs which are collectively diagnostic, namely, digestive disturbances, pain, emesis, hæmatemesis and a gastric tumor. Digestive disturbances, due to the neoplasm or to coexisting gastritis, are often the first symptoms. The appetite is impaired, perverted, or lost more frequently than in gastric ulcer. Sometimes, particularly if the cancer be at the cardiac orifice of the stomach, there is no loss of appetite. There are often epigastric discomfort, eructation, pyrosis, and nausea before the appearance of actual pain or emesis. Sooner or later, however, pain almost always becomes a prominent symptom. Brinton estimates that pain occurs in ninety-two per cent., and Lebert in seventy-five per cent., of all cases. It is probably most apt to be absent when the cancerous growths do not involve the orifices of the stomach. The pain may be either dull or lancinating, constant or paroxysmal. It is generally referred to the epigastrium, but often to the hypochondria, the loins, the mediastinum, the back, and even to more remote regions. The location of the pain does not, therefore, afford great assistance in exactly locating the cancerous tumor. When intermittent, the pain is frequently excited, and, when constant, is aggravated, by the ingestion of food. Pain is ordinarily more constant in the later stages of the disease, when ulceration has occurred, than at earlier periods of the malady. Vomiting occurs, according to Lebert, in eighty per cent. of all cases, appearing most constantly when either the pylorus or the cardiac orifice is diseased. In many instances emesis is rare, or absent, in the earlier stages, but begins or increases in frequency and violence as the disease advances. When the cancer is situated at the cardiac orifice, vomiting often, but not invariably, immediately follows the ingestion of food. In this case the food may not enter the stomach, but, encountering the cancerous obstruction at the cardiac orifice, is returned by reversed peristaltic movements of the œsophagus. In pyloric cancer vomiting usually occurs later than in carcinoma of the cardiac orifice, generally an hour or more after meals, but this rule has frequent exceptions. It is thus evident that the time when emesis occurs does not afford material assistance in locating gastric cancer. If gastrectasia has followed malignant pyloric stenosis, the vomiting naturally takes place after much longer intervals and is more copious, as is the rule in obstructive dilatation. The vomited matters consist, at first, of undigested food mingled with mucus and epithelium. Later, sarcinæ, torulæ, abnormal acids and gases are present, and in forty-two per cent. of the cases, according to Brinton, blood, which having been acted on by the gastric juice presents the familiar coffee-ground or chocolate-like appearance. In the majority of cases gastrorrhagia from cancerous ulceration is not profuse, the blood escaping from capillaries eroded by the process of ulceration. Commonly, however, the blood is present in sufficient quantities to be recognized by the naked eye, but in some cases an appeal to the microscope or the spectroscope may be necessary to decide the question. The spectrum produced by alkaline solutions of hæmatin shows an absorption band between C and D, which some-

times extends beyond D. The microscopic test for hæmin is made as follows: An excess of glacial acetic acid and a few grains of sodium chloride are added to the suspected liquid, and boiled in a test-tube. If blood-pigment is present, microscopic crystals of hæmin will be deposited by the cooled liquid, and may be recognized by their rhombic form and dark-brown color. Profuse hæmorrhages occur, according to Lebert, in only twelve per cent. of all cases of gastric cancer, men being more liable to them than women. Copious hæmatemesis is most often caused by soft cancers seated at the pylorus or on the lesser curvature, and generally takes place at a late stage of the disease. Gastrorrhagia may sometimes be fatal, and may even cause death, without occasioning hæmatemesis. Rosenbach recognized, in three cancer cases, fragments of cancerous structures in matters withdrawn from the stomach by the tube, and similar fragments have, very rarely, been seen by other observers.

Van der Velden claims that free hydrochloric acid is habitually absent in cases of gastrectasia from cancerous pyloric obstruction, but Seaman and others have detected hydrochloric acid in stomachs dilated by this cause, and the relative frequency with which this acid is absent in gastric cancer unaccompanied by dilatation remains to be ascertained. The view at present held by the majority of the profession, regarding this question, is apparently to the effect that habitual presence of hydrochloric acid in fluids taken from a dilated stomach renders the existence of cancer improbable. The absence of the acid cannot, however, be regarded as diagnostic of carcinoma, since it also occurs in chronic gastritis, in fevers and in other diseases. Rough clinical tests for free hydrochloric acid have been described under the treatment of chronic gastritis. There are, however, many sources of error in applying the more reliable and complicated tests for the detection of the acid, and it is therefore to be recommended that physicians employ competent chemists to make the necessary tests. The digestive power of the gastric juice is usually notably impaired in cancer cases, which naturally follows from the absence of hydrochloric acid. Riegel states that the gastric juice from a cancerous stomach, if added to normal gastric juice, even notably retards the action of the latter. The digestive power of gastric juice may be tested by suspending, in the filtered gastric fluids, a piece of fibrin, the temperature of the filtrate being maintained at about 100° F. If free hydrochloric acid is present the proteid will soon begin to dissolve. The most important sign of cancer in the stomach is a gastric tumor. This sign is never perceptible in the earlier stages, but can be discovered in about eighty per cent. of all cases at some period of the disease. Tumors placed at the cardiac orifice, at the fundus, on the posterior wall, or at the lesser curvature, near the pylorus, may escape observation, because hidden beneath the liver or behind the border of the ribs. If the neoplasm grows chiefly into the lumen of the stomach, it may likewise escape detection. In diffuse cancerous infiltration of the gastric walls no localized tumor is perceived, but a peculiar resistance and induration, corresponding to the seat of the stomach, may sometimes be appreciated. Pyloric tumors are felt more often than others. This is true partly because, even if a pyloric neoplasm be at first covered by the liver, it may later become palpable by displacing the pylorus downward. The tumor is ordinarily felt in the epigastrium, sometimes to the right and sometimes to the left of the median line, but may, owing to downward displacement of the stomach, be found in various other abdominal regions. In some instances the tumor is movable, changing its position according to the varying distention of the stomach and of the colon. When adhesions exist between the cancer and the liver or the diaphragm, the tumor follows the respiratory diaphragmatic movements. More frequently, however, the cancer is immovable, being fixed by adhesions. The tumor is generally small and nodular, occasionally smooth. Ulceration often causes perceptible diminution in the size of a tumor.

Percussion over the tumor occasionally yields a flat note, commonly, however, a dull one. The urine often has an abnormally small amount of urea and contains albumin, indican, and, according to V. Jacksch, diacetic acid, to which coma, occasionally observed at the end of cancer cases, is attributed by some authors. The bowels are ordinarily constipated, but often constipation alternates with diarrhœa. The temperature is often normal during the entire course of the disease. Sometimes, however, there are slight chills, followed by elevation of temperature. As death approaches, the temperature may become subnormal. Cancer of the stomach causes marked anæmia, extreme emaciation and great asthenia, and imparts a more or less characteristic color to the skin. This cachectic appearance is not pathognomonic of carcinoma, as it may occur in non-cancerous pyloric stenosis and in ulcer. Thromboses of the veins of the thigh and leg are common, but hydræmic œdema of the feet and legs may occur independently of this. Dysphagia occurs in many cases, chiefly when the cancer involves the cardiac region of the stomach. The patient's mental powers are generally not impaired by the disease, but he is usually depressed and melancholy. Gastric cancer may perforate the stomach, causing peritonitis or any of the inflammatory complications and fistulous communications mentioned as possible results of perforation by an ulcer. Gastro-colic fistula is more common with cancer than with ulcer. Perforation of the stomach occurs much more rarely with cancer than from ulcer. Fatal gastrorrhagia from erosion of blood-vessels occurs in only about one per cent. of all cases of gastric cancer. The symptoms due to metastatic cancerous tumors of the liver, of the peritoneum, of the lymphatic glands, of the pancreas and of the lungs are to be sought in the articles in this HANDBOOK devoted to these respective subjects.

Differential Diagnosis.—This involves the exclusion of other gastric diseases and of tumors not connected with the stomach. The gastric diseases most likely to be mistaken for cancer are ulcer, simple chronic gastritis, chronic interstitial gastritis, gastrectasia from non-malignant pyloric stenosis, gastralgia, and other gastric neoplasms. The chief points of distinction between gastric cancer and ulcer are the following: The age of patients with ulcer is under forty in about one-half the cases, while cancer is rare until after the fortieth year. In cancer, vomiting is less frequent than in ulcer, and commonly occurs later after the ingestion of food. Gastrorrhagia is more frequent in cancer, but less profuse. In cancer the vomited matters may contain cancerous fragments and be devoid of hydrochloric acid. The pain of cancer is more constant, is less affected by eating, is more diffuse, and is less relieved by emesis than that of ulcer. A gastric tumor is present in eighty per cent. of cancers of the stomach, but a tumor is rare with ulcer. The maximum duration of cancer is about a year and a half; that of ulcer may be much longer. Appropriate treatment commonly relieves the symptoms of ulcer, but not those of cancer. The cachexia of carcinoma is more marked, and not so directly referable to the gastric symptoms. Secondary growths are often found in other organs with cancer, but not with ulcer. The fact is to be constantly borne in mind that a cancer may develop from the margins or from the cicatrix of an ulcer, in which case the clinical history of the latter gradually merges into that of the former. In simple chronic gastritis the vomited matters frequently contain hydrochloric acid and never cancerous fragments; gastrorrhagia is rare, and the pain is both less severe and less localized than in cancer. Gastritis occurs at all ages indifferently, has no tumor, and may continue indefinitely, but is more readily controlled by treatment than is cancer. Gastritis produces no marked cachexia, and is not attended by secondary growths. Chronic interstitial gastritis sometimes presents a smooth, resisting tumor, possessing the shape and outlines of the stomach, but can hardly be differentiated from diffuse gastric cancer. It generally tends to diminish the size of the stomach, is of longer duration, and is usually not accompanied by gastrorrhagia or by severe pain. Simple gastralgia generally has none of the symptoms of carcinoma except the pain. Gastrectasia following non-malignant pyloric obstructions is ordinarily due

to antecedent ulcer, the history of which may be obtained. It also commonly occurs before forty rather than after that age. The other gastric neoplasms are so rare that they are clinical curiosities, and their differential diagnoses need not be discussed. If they are so situated as to cause pyloric stenosis, they can hardly be distinguished from cancer. The tumors of other organs most likely to be mistaken for gastric cancer are those of the liver, the pancreas, the peritoneum, the aorta, the intestine, the retroperitoneal lymphatic glands and the omentum. Even renal and splenic tumors may be included in this category. For the differential diagnosis of these neoplasms the reader is referred to the writer's article on Abdominal Tumors, in the first volume of this HANDBOOK. The diagnostician should always bear in mind the possibility that secondary cancerous tumors, developing in any of these organs, may quite obscure the original gastric carcinoma. It is usually impossible to diagnosticate the variety of cancer existing in a given case, nor is it especially useful to make the distinction. In very rare cases the variety of cancer may perhaps be ascertained by an examination of the carcinomatous fragments found in the fluids withdrawn from the stomach.

Prognosis and Duration.—There is no authentic record of recovery from gastric cancer. Billroth successfully performed pylorectomy for gastric carcinoma in 1881, and the operation has been successfully done several times since then. In the majority of the cases, however, the operation has been fatal, and in no case has an ultimate cure been effected, although life has undoubtedly been considerably prolonged by this surgical interference. It is possible that a radical cure may sometimes be attained by early pylorectomy in favorable cases, but the diagnosis is so frequently in doubt until secondary deposits have occurred that there is little probability of a decided reduction in the mortality of gastric cancer by operative treatment. The duration of gastric carcinoma can often only be approximately estimated, because the disease frequently remains latent for a long time. On the other hand, in cancers developing from ulcers the carcinoma may be regarded as the original disease, and a correspondingly long duration be ascribed to it. Lebert estimates the average duration at fifteen months, and the maximum duration at four years. Brinton places the average duration at twelve and a half, and the maximum duration at thirty-six months.

Treatment.—There is no known specific for gastric cancer, and all treatment must consequently be symptomatic. The indications are, as in ulcer, to prevent gastritis by bland aliment, to relieve pain, to check emesis and to control hæmatemesis; to sustain the patient's strength, and to meet other symptomatic indications as they arise. The most suitable articles of diet are those recommended under the treatment of gastric ulcer. Pain is to be relieved by morphia, preferably given hypodermatically. Vomiting is to be checked by opium, counter-irritants, a regulated diet, and, if otherwise uncontrollable, by rectal alimentation. Hæmorrhage, if profuse, and perforation require the same treatment suggested for pain and gastrorrhagia from gastric ulcer. The same remark applies to inflammatory complications of abdominal or thoracic organs. Constipation calls for laxative enemata, and diarrhœa for opium and bismuth, or for starch and laudanum enemata. For pyrosis, alkalies are valuable. Lavage, by means of the soft tube, unless contra-indicated by profuse gastrorrhagia, or by great asthenia, is useful in relieving gastritis and in preventing the development of gastrectasia. Operative interference, to be of avail, must be undertaken early, before glandular infiltration has occurred. If an early and reasonably certain diagnosis of cancer is made, it is justifiable to perform laparotomy, in order to decide upon the propriety and necessity of an operation. In the hands of experienced surgeons this laparotomy is devoid of serious dangers.

OTHER GASTRIC NEOPLASMS.—The most common non-malignant gastric new-growths are mucous or submucous adenomata and myomata. Fibromata, lipomata, cystomata and miliary aneurisms are rarely observed. Primary or secondary sarcomata and myo-sarcomata are also infrequent. These neoplasms have little clinical significance, owing to their rarity and to their ordinarily small size. The differential diagnosis between carcinoma and these new-growths cannot ordinarily be made with any certainty, and their treatment, when recognized, is the same as that recommended for cancer.

ATROPHY OF THE STOMACH AND DEGENERATION OF THE GASTRIC TUBES.—Atrophy of the entire stomach, from disuse, may follow stenosis of the œsophagus or of the cardiac orifice. The general atrophy of marasmus and of senility may also involve the stomach. The gastric tubules frequently undergo parenchymatous and fatty degeneration in the acute infectious diseases, such as typhus and typhoid fevers, yellow fever, septicæmia, and the eruptive fevers, and in poisoning with phosphorus, arsenic, mercury and the mineral acids. The tubules are gradually restored to their natural condition after the subsidence of these febrile disorders or the elimination of the poisons causing the degenerations. It is reasonable to assume that the digestive disturbances observed in cases of the above maladies are in large measure due to failure in the functional activity of the gastric secreting cells. Allusion has been already made, in the appropriate sections, to the degenerative and atrophic changes in the tubules accompanying chronic gastritis, interstitial gastritis, phlegmonous gastritis, ulcer and carcinoma. As early as 1860, Dr. A. Flint, Sr., advanced the opinion that degeneration of the gastric tubules would prove to be the anatomical basis of certain cases classed as pernicious anæmia. The subsequent investigations of Fenwick, Quincke, Brabazon and others support this view. In some of the recorded cases the atrophy has been attended by increase of the interstitial gastric connective tissue, but in other cases this was wanting. The absolute demonstration of the existence of primary atrophy of the tubules has, however, in the writer's opinion, not yet been furnished. The general symptoms which have been referred to atrophy of the gastric tubules are those of pernicious anæmia, the digestive symptoms being anorexia with occasional vomiting, eructation and epigastric pain. It is exceedingly difficult, in these cases, to decide whether the anæmia may not have caused sufficient disturbance of nutrition to produce the local atrophy, rather than that the reverse conditions obtained. This is one of the problems now engaging general attention on the part of the profession, and which it is to be hoped may eventually meet with a satisfactory solution.

RUPTURE OF THE STOMACH.—Perforation of the stomach may occur, as has been stated in the appropriate sections, from diseases affecting its parietes, such as ulcer, cancer, toxic gastritis and suppurative gastritis. Rupture of a healthy stomach may occur from severe abdominal injuries, with or without perforation of the abdominal walls. Thus, heavy weights falling from a height, the wheel of a heavy vehicle—or the buffers between railway carriages—being brought violently in contact with the abdomen, may rupture the stomach in common with other viscera, or, in rare cases, the stomach alone. There are no satisfactory records of spontaneous rupture occurring in a stomach with healthy walls, although many cases of supposed spontaneous rupture have been reported. In the majority of these cases the pathological anatomical conditions were not carefully investigated, and it is probable that pre-existing lesions were responsible for the accidents. Leube performed experiments upon the cadaver in order to test the resisting capacity of the stomach, and found that enormous distention of the organ could be produced by hydraulic pressure without occasioning rupture. In these experiments the mucous membrane and the serosa yielded to the pressure, while the muscular coat remained intact. The writer has seen a case of atonic gastrectasia in which the distention of the stomach was such as to cause intense suffering, with extreme tenderness over the organ, which reached to the iliac crest. In this case the pain and the other symptoms were such that rupture was regarded as imminent, and the tube was at once introduced. After the escape of an immense amount of gas the pain at once

subsided, whereupon nearly three gallons of liquids and solids were withdrawn by the siphon. The symptoms of rupture of the stomach are identical with those of perforation, already described. The prognosis is fatal, and the treatment must consist in the free administration of morphine hypodermatically, with a view to promoting euthanasia.

William H. Flint.

STOMATITIS. This word, which from its derivation signifies inflammation of the mouth, is held to include inflammatory affections of the cavity of the mouth as far back as the soft palate. Any abnormal condition of an inflammatory character which involves the gums, the tongue, or the inner surface of the cheeks, is included, therefore, under the designation of stomatitis. Experience shows that there is little tendency toward limitation to any one of these structures—usually the entire cavity of the mouth partakes of the diseased condition.

The affections included under this name are, in great part, limited to the age of childhood. Adults are never the subjects of certain forms of the disease, and seldom suffer from any variety of it, save as part of some other morbid condition. Not infrequently, however, stomatitis is nothing more than a part of such general condition. Diphtheria sometimes involves the mouth as well as the tonsils, pharynx, and palate; inflammation, with pustulation in the mouth, may occur in small-pox, varioloid, and varicella; facial erysipelas often presents an inflamed condition of the mouth; measles, Rötheln, and syphilis are accompanied by characteristic mouth affections; and many drugs, such as mercury and iodine, in addition to the mineral and other stronger acids, produce an abnormal condition.

These various conditions do not come within the province of the present article, and for their consideration the reader is referred to the articles treating of the various diseases mentioned.

What may be called primary stomatitis, as distinguished from the above-mentioned conditions, being practically a distinct disease, is encountered in the following varieties:

I. Simple, catarrhal, or erythematous.
II. Membranous, or ulcero-membranous.
III. Ulcerative.
IV. Gangrenous.

I. CATARRHAL STOMATITIS.—By this we mean that form which does not present exudation or ulceration. It is seen occasionally as a result of taking cold, being part of a general inflammation of the respiratory mucous membrane; it is sometimes associated with chronic alco-

holism; it may be caused by excessive eating of acid fruits and highly seasoned articles of food; and in children it is frequently an attendant upon difficult dentition.

Its symptoms are: Redness and capillary injection of the mucous membrane; swelling of the tongue, cheeks, gums, and lips; dryness of the cavity of the mouth, especially at first, and later sometimes increased flow of saliva and mucus, especially in the case of teething children. If the swelling, which is flabby, be marked, the impression of the teeth may be seen on the tongue and cheeks. The sense of taste is often diminished, and is sometimes perverted—patients stating that meats, etc., have a putrid flavor. The amount of pain is not great in this variety of the disease, and is often entirely absent, particularly in the chronic stomatitis of excessive drinkers. Occasionally the salivation is a source of annoyance, as in the stomatitis of difficult dentition.

As to treatment, over and above that addressed to the causative agency, the means to be used are the moistening of the mouth with cold water, the administration of chlorate of potassium, and often the application of astringent washes, such as a weak solution of sulphate of zinc or copper.

II. Membranous, or Ulcero-membranous Stomatitis.—Diphtheritic membrane may involve the anterior aspect of the soft palate, and sometimes spreads forward over the cheeks and tongue. Thrush, which is characterized by the formation of a white pellicle or membrane in patches, is most frequently visible on the tongue. Both these diseases are certainly membranous forms of stomatitis, but the term is here employed to indicate an affection distinct from these, and local in its nature. Diphtheria and thrush are described elsewhere in this work.

Ulcero-membranous stomatitis, in this restricted sense, is a disease characterized by the production of discrete patches of thick, yellowish, pseudo-membrane or exudation, which apparently becomes separated from the subjacent tissues by an ulcerative process, leaving erosions on the surface formerly occupied by the exudation.

As to causation, it is to be attributed to bad hygienic surroundings, to improper and insufficient nourishment, and is generally met with in hospital patients, and but very rarely among people in more comfortable circumstances. It has clearly an epidemic character, as usually a number of cases will be encountered at or near the same time; and, on the other hand, long periods will elapse without the occurrence of a single case. Convalescence from acute diseases is thought to be a condition predisposing to its occurrence.

Like other forms of stomatitis, it is in the main an affection of childhood, though not of infancy; the usual time of its occurrence being between the ages of five and ten years.

The disease generally begins with pain and discomfort in the gums, made prominent by the act of mastication. The gums are seen to be reddened and swollen, and are tender to the touch—in short, a condition of gingivitis is present. There is commonly a slight rise of temperature. Then a grayish or yellowish exudation makes its appearance on the gums, which spreads to the adjacent parts of the cheeks and inner surface of the lips; and occasionally even involves the palate and pharynx. If this pseudo-membrane be detached, the subjacent mucous membrane is found to present an excoriated and ulcerated appearance.

If the case be a mild one, the area covered by the exudation is not great, the ulcerations are neither large nor deep, the other symptoms are not severe, the course is rapid, and complete restoration to the normal condition occurs within a few days.

On the other hand, in a severe case the exudation spreads widely, the ulcerations become deep, foul, and extensive; the breath is offensive, the odor sometimes being almost gangrenous; the saliva is greatly increased in amount, is offensive in odor, and discolored; the salivary and submaxillary glands become enlarged and tender, and the swelling, stiffness, and pain in the jaws are marked. Such a case may be protracted for a month or more, and may closely resemble true gangrenous stomatitis—possibly may run into that disease. The similarity between the two conditions may be very great, and the points of difference in the matter of diagnosis will be mentioned below, in the description of the latter disease.

The prognosis is favorable, even in the severe form, if true gangrene do not supervene.

The treatment is, in the first place, to be addressed to the general condition of ill-health spoken of as having a causative relation. Nourishment, of good quality and quantity, should be first provided for; stimulants may be necessary; tonics, as the compound tincture of cinchona or the tincture of nux vomica, are usually of considerable assistance; and the administration of iron is advisable. As to local treatment, the most serviceable drug is the chlorate of potassium, which should be given in considerable quantity—two or three grains every two or three hours. In addition to this, local astringent washes, as a solution of sulphate of copper (five grains to the ounce), or the honey of borax, should be used freely. Chloride of lime is highly spoken of as a cleansing agent.

III. Ulcerative inflammation constitutes an essential part of the variety of stomatitis just described, and, as will be seen, is also present in the gangrenous form. Ulceration occurs also in aphthæ, and in children this is by far the most frequent form of ulcerative stomatitis. Finally, small ulcerations are formed by the breaking of herpetic vesicles, which occasionally appear in the mouth as well as on the lips. These are popularly known as "canker sores," are always small in size, and remain but a short time. To touch them once or twice with solid sulphate of copper or nitrate of silver is sufficient to cause them to heal readily and quickly.

IV. Gangrenous Stomatitis.—This grave disease has a variety of names, the two in most frequent use being cancrum oris and noma; it is occasionally called cancer aquaticus, or water cancer.

It is a true gangrene or sphacelation, affecting the jaws and cheeks, and sometimes spreading widely and with great rapidity. It occurs, like the ulcero-membranous form of stomatitis, in children only, and in those in bad general condition and living in bad hygienic surroundings; and, in the great majority of cases, develops during convalescence from some one of the acute febrile diseases. Of such antecedent affections measles is the most frequent; it being estimated that one-half the cases follow this disease. Pneumonia, though very often a concomitant of the gangrenous disease itself, sometimes precedes it, and typhus fever is said to be occasionally followed by gangrenous stomatitis. It is asserted by some that the affection may become developed in severe forms of mercurial sore mouth, but such instances must be rare, for mercurial ptyalism is usually amenable to treatment. Sometimes it is encountered in such a manner as to appear to be epidemic; in this bearing some resemblance to hospital gangrene.

It is an affection of childhood, occurring in the period of second dentition, and is rarely, if ever, seen in a child under one or two years of age, or over ten or eleven.

The disease is generally unilateral—not extending across the middle line of the lips. It is considered by many to be independent of thrombosis or embolism of the blood-vessels, such as causes gangrene elsewhere, and under different conditions. Yet there must be, seemingly, some circulatory disturbances to account for it, since the unilateral character is almost invariable; from which we may reasonably argue that the circulation on the unaffected side is maintained in proper degree, while the death of tissue on the diseased side is evidently due to defective nutrition. Moreover, after death the arteries are found to contain more or less firm clots, and before death hæmorrhage does not occur when a vessel is opened by erosion.

Gangrene of the mouth does not begin with active inflammation, and absence of pain is quite characteristic; often the existence of the disease is not suspected until the destructive process has become far advanced. If seen

at the outset, its first appearance is that of a vesicle or bleb, which soon breaks, leaving an ulceration on the gum or inner surface of the cheek, or frequently at the line of junction of the two. Some degree of swelling of the face soon shows itself, the breath almost immediately becomes fetid, and soon acquires a gangrenous odor. With the bad general condition there is but little fever or pain, and a pronounced condition of prostration does not develop at once. On the contrary, the child usually sits up and takes its nourishment quite readily. The foul ulceration spreads, often with great rapidity, and soon the substance of the cheek presents a circumscribed, hard, tense, and shining swelling or infiltration, of a dark red color, with one or more bluish spots soon appearing—which are in reality dead tissue. Sometimes only two or three days are needed for this condition to be attained. The saliva is increased in quantity, is blood-stained and dark, and most offensive in odor; and the submaxillary and salivary glands become enlarged. Thirst is constant, and is most distressing to the patient, and often an exhausting diarrhœa, difficult to control, sets in, increasing, of course, the prostration.

The intelligence remains generally undisturbed, and the little patients do not seem to be greatly alarmed, but rather apathetic. The temperature and respiration become influenced principally because of, and in proportion to, pneumonic inflammation of the lungs, which, as stated, is frequently a precedent and concomitant condition. This associated pulmonary inflammation is, however, never of the sthenic type of simple acute lobar pneumonia.

The appearance of an eschar on the skin of the cheek, usually at or near the angle of the mouth, is characteristic, and is an indication of the extension of the gangrene through the thickness of the cheek. This may occur in as short a time as two or three days. The eschar continues to spread, and may, indeed, advance with such rapidity that from three to six days suffice for the destructive process to be complete. Such rapid progress is not, however, the rule, and ordinarily the entire duration is from one to two weeks in cases terminating in death, which almost always occurs.

Together with the sphacelation of the soft parts, necrosis of the maxillary bones takes place. The bone becomes diseased, and presents a worm-eaten appearance, and the teeth loosen and can be removed from their sockets. The tongue, however, remains uninjured.

Profuse hæmorrhage is very rare, though there is always some oozing of blood, which discolors the saliva. As stated, the arteries are found after death to contain clots of considerable firmness.

When the disease has advanced, the odor of the patient's breath is more than fetid and offensive—it is distinctly gangrenous.

Recovery is a remarkable event, occurring, according to most authorities, in about one case in twenty. If the characteristic eschar appear on the skin of the cheek, very little hope can be entertained.

Death occurs from asthenia, after a duration of from one to two weeks, and is often hastened by the lung inflammation which so frequently occurs. In the few cases which recover, the disease is greatly prolonged, and after the final healing of the affected part much cicatrization and disfigurement remain.

A similar gangrenous disease, in rare instances, invades the genital region in girls (noma vulvæ), and runs the same severe course, with generally a fatal termination.

The diagnosis of gangrenous stomatitis is usually not difficult. The conditions bearing a resemblance to it are: The bad form of ulcero-membranous stomatitis, and serious and aggravated cases of mercurial sore mouth. From the former, discrimination is to be based on the absence of pseudo-membrane, the rapid and deep extension of the ulcerative process, the perforation of the cheek, and the hard, smooth, dark, and shining swelling. Also, in the simpler disease, no necrosis of the jaw nor loosening of the teeth occurs. Ulceration from mercurial poisoning has an antecedent stage of salivation, is bilateral, and does not spread rapidly and extensively, nor does it perforate the cheek like gangrenous stomatitis.

The treatment of gangrenous stomatitis, though not satisfactory, must yet be energetic. It consists of general and local measures. The former include the carrying of nutrition to the highest possible point, by urging the patient to drink most freely of milk and cream of good quality; to take concentrated fluid preparations made from meat; and, if it can be done without interference with digestion or discomfort in eating, to take bread and farinaceous articles of food. Stimulants are almost always admissible from the first, and generally have to be given with a free hand. A child five years of age can take two teaspoonfuls of brandy every two or three hours, and if the prostration be great, a still larger quantity. The better plan is to give the liquid nourishment in stated quantities at intervals of about two hours, so that one or two quarts of milk are administered in the twenty-four hours.

The principal part of the local treatment consists in the thorough application of cauterizing agents to the diseased surface. The earlier and the more thoroughly this is done, the better is the chance (slight though it is) of altering the character of the eroded surface, and converting it into a simpler form of ulcerative process.

The agent most frequently used is nitric acid, applied over the entire diseased surface, the surrounding healthy tissues being protected by oil or vaseline. The application must be thorough to be of any value, and the utmost care is necessary to prevent injury to the sound parts. The mouth should be carefully and copiously syringed out with water after the cauterization. Other escharotics, as muriatic and pure carbolic acid, can be employed, as well as the actual cautery or galvano-cautery. Usually authorities advise frequent cauterization—sometimes as often as twice a day—but, on the other hand, the statement has been made that no greater proportion of recoveries results among those treated by this means than among those in whom it is not resorted to. It should, however, be looked upon as a plan of treatment affording at least a chance of recovery from what is almost a hopeless disease.

In addition, constant antiseptic washing of the mouth should be enforced, since a part at least of the asthenic condition and prostration can be attributed to septic absorption. Simple salt and water, weak solutions of carbolic acid, of bichloride of mercury, or of boracic acid, should be liberally used. Chlorate of potassium and the tincture of the chloride of iron should also be given.

STORAX (*Styrax*, U. S. Ph.; *Styrax Præparatus*, Br. Ph.; *Styrax Liquidus*, Ph. G.; *Styrax liquide*, Codex Med.). "A balsam prepared from the inner bark of *Liquidambar orientalis* Miller; Order, *Hamamelaceæ*."

This is a bushy, middling-sized tree, resembling a maple or plane tree, with smooth, purplish-gray bark, and maple-like, lobed, smooth, stipulate leaves. Flowers minute, the sterile of numerous stamens only, the fertile of a short calyx-tube and two several-ovuled carpels. They are arranged in compact globose clusters, which, as they ripen, form compound fruits of the coalescing calices and pistils.

This tree is a native of the Southwest districts of Asia Minor, where it forms forests. Its range seems to be quite a small one, not extending to the north or to the islands of the Levant.

The name Storax (Styrax) has for many centuries been applied to two quite distinct substances: The resin of *Styrax Officinalis* Linn., a solid, benzoin-like balsam which has become obsolete, and the present complex liquid called for distinction Liquid Storax. This is collected by removing the outer bark from the tree, then scraping off the inner bark and boiling it with water from the sea. The resin melted out from the bark separates from the watery liquid and is skimmed off. The bark is then pressed and a further amount obtained.

Storax prepared in this way is a soft, resinous compound

FIG. 3735.—Storax: leaves and flowers. (Baillon.)

of peculiar balsamic, agreeable odor, having a honey-like consistence and a pungent, burning taste. It is opaque, of a grayish-brown color, and contains considerable water entangled in it, to which its opacity is due. Upon long standing or heating the water may be driven off, and a clear yellow or brown resin remains behind. In odor it improves with age. It always remains sticky. This balsam consists principally of an amorphous substance named *storesin*. It also contains several *cinnamic ethers* and *cinnamate of cinnamyl* (styracin), which can be prepared in rectangular prisms, and *cinnamic acid* and *styrol*.

Storax goes principally to the East, very little being used in European pharmacy; in its action it varies very

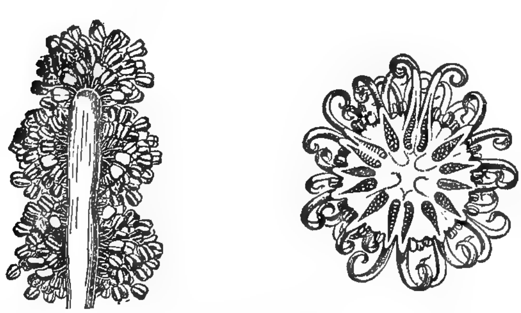

FIG. 3736.—Storax; staminate and pistillate clusters enlarged. (Baillon.)

little from a number of other resinous substances; internally it has been used in bronchitis and similar conditions with but moderate success. As an ingredient of liniments, ointments, etc., it is quite useful. The compound tincture of benzoin contains eight per cent. of storax. Dose of storax, from three to five drops.

ALLIED PLANTS.—The Sweet Gum Tree, *Liquidambar Styraciflua* Linn., resembles the above species and supplies a non-drying sticky resin resembling storax in medicinal properties, although not in color or opacity. *Hamamelis Virginica*, Witch-Hazel, belongs to a related Genus.

ALLIED DRUGS.—Numerous balsams, resins, turpentines, etc., resemble this in their action; perhaps the nearest is *Balsam of Peru*, q. v. *W. P. Bolles.*

STRABISMUS, or **SQUINT**, is that condition in which the visual axes are not both directed toward the point looked at; its peculiar subjective symptom is diplopia, and objectively the eyes may be seen to be turned in different directions.

Diplopia arising from strabismus is binocular, and is noticed only when light from the object looked at falls on both eyes and is sufficiently well focussed by both to form a sensible image on the retina; when both retinal images cause the proper impression on the visual centres; and when these visual centres are so related to each other as to possess the power of binocular fusion. If, when one eye is excluded from vision by closing it or covering it with an opaque object, the double vision still remains, it is monocular and has nothing to do with strabismus.

Normally, when a certain point is looked at, or fixed, the visual axes of both eyes pass through that point and in each eye its image falls on the retina at the fovea centralis; and the impressions thus received produce in consciousness the idea of a single point. When, however, the point looked at makes its impression on the fovea in one eye, but on some other portion of the retina in the other, it generates the idea of two distinct points some distance apart, the impression on the fovea being referred to a point directly in front of the eyes, while the impression on another part of the retina is referred in a different direction, giving rise to the idea of the duplication of the point looked at, called diplopia or double vision. Thus in Fig. 3737, representing a case of convergent strabismus, the visual

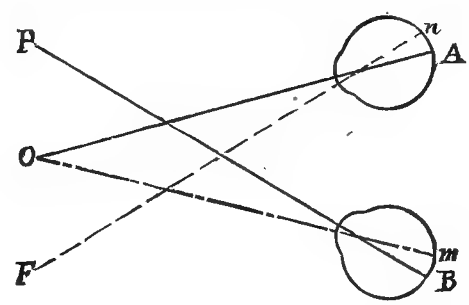

FIG. 3737.

axis of the eye A being directed to the object O, the visual axis of the eye B is directed elsewhere to P.

In the eye A the impression of the point O will be made at the fovea; but in the eye B the light from O, entering in the direction of the broken line O *m*, will make its impression on the point *m*, some distance from the fovea. Since the impression is made on A at the fovea, it will be correctly referred to the object looked at. But in B the impression made at *m* will be referred to a point to one side of the object looked at; its position relative to O being in the direction *n* F, which makes the same angle with the visual axis of A as O *m* makes with the visual axis of B. The image of the point received on A, and referred to its true position O, is called the *true image*. The image received at *m*, and referred to F, in the direction *n* F, is called the *false image*.

In Fig. 3738, representing what occurs in divergent squint, the eye A, turned toward the object O, receives on its fovea the true image, which is referred to its proper source; and the eye B receives at *m* the false image, which, with reference to the true image, is referred in the direction *n* F to F.

In either case, when the deviating or squinting eye is turned to the right, the false image appears to belong to an object to the left of that which causes the true image;

and when the deviating eye turns to the left, the false image seems to be to the right of the object. When an eye deviates upward its false image appears below; and when it deviates downward the false image appears above. In general, in whichever direction the squinting eye deviates, its false image appears to be situated to the opposite side of the true one. When the image on the right side belongs to the right eye, it is called *homonymous diplopia*. It occurs when the visual axes are crossed as in Fig. 3737. When the image on the right side belongs to the left eye, and the image seen to the left belongs to the right eye, it is *crossed diplopia*. This is represented in Fig. 3738, and occurs in divergent squint. To determine

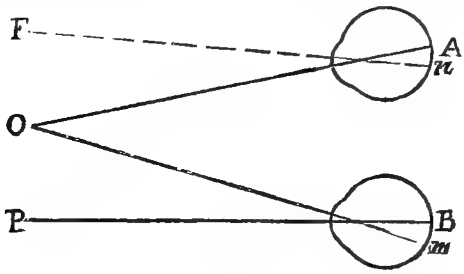

FIG. 3738.

which image belongs to the right eye, and which to the left, cover one eye and the image belonging to it will instantly disappear. Another method of identifying the images is to place before one eye a piece of colored glass, when the image belonging to that eye will instantly appear colored. In making these tests for diplopia a candle or lamp flame is an excellent object to have the patient look at.

Objective Symptoms.—If the squint be well marked, inspection, sometimes the most casual, will reveal the defect, and show which eye it is that deviates. But even in what may seem to be an unmistakable case there is a possibility of error. We judge of the direction of the visual axis by the direction of the centre of the cornea; and usually the visual axis pierces the cornea near its centre, or a very little to the nasal side of the centre. But sometimes the visual axis deviates considerably from its usual direction, so that, when it is properly directed toward the object fixed, the centre of the cornea will be turned considerably to one side, and the eye will appear to squint. Or the centre of the cornea will be turned apparently in the right direction, and the visual axis will really deviate considerably from the object looked at.

To determine whether the eye really does squint, direct the patient to gaze steadily at a certain object in front of him, and cover first one eye and then the other. If both eyes are properly directed toward the object, there will be no change of position when either one is covered. If one eye have its visual axis turned elsewhere, covering it will not cause any change of position; but covering the eye which has been really directed toward the object will cause the eyes or head to be turned, so that the eye which had looked elsewhere may now fix on the object. If, however, both eyes have been fixed on the object, but only by an undue effort, the covered eye will deviate and take such position as can be preserved without the undue effort. The objective test of covering the eyes alternately while fixed upon some point and watching their behavior should be repeated until the observer is satisfied as to the presence or absence of squint. Having ascertained that squint is actually present, the first point to be settled is whether it is *concomitant* or *paralytic*.

CONCOMITANT STRABISMUS is a wrong, and usually variable, co-ordination of the movements of the eyes with reference to each other, without marked limitation of these movements in any particular direction. In general, it is to be noticed whatever the direction of the object looked at, but its amount may vary from time to time, and is often greater the nearer the object is to the eye. It commonly appears in early childhood, but may exist from birth, and more rarely begins during adult life.

Convergent squint is the most common form of concomitant strabismus. In it the visual axes, instead of converging to the point looked at, converge to and cross at a point nearer the eye, as in Fig. 3737. In it the diplopia is homonymous, and on covering the eye which is fixed on the object it turns in toward the nose, while the other turns from the nose and fixes the object.

Divergent squint comes next to the convergent in frequency. In this form the visual axes do not converge enough, either meeting at some point beyond the object looked at, or remaining parallel or even divergent; the diplopia is crossed, and when the fixing eye is covered it turns out toward the temple, diverges, and the other eye turns toward the nose and fixes the object. When the visual axes remain always divergent, no matter how great an effort is made to turn them in, the squint is said to be *absolutely divergent*. When the visual axes can be made to converge, but not to converge enough for the visual axes both to pass through the point looked at, as in Fig. 3738, the squint is said to be *relatively divergent*. *Parallel squint* is the name formerly applied to those cases of relative divergence in which the visual axes remain parallel when they should converge toward a near object.

Vertical squint, in which one visual axis is directed more upward or more downward than the other, is exceedingly rare, except as complicating one of the other forms of concomitant squint. It is quite common in divergent squint to find the eye which habitually deviates to be turned upward, as well as outward; and, as this condition is frequently associated with drooping of the upper lid, it has been regarded as an effort of nature to exclude the deviating eye from vision and thus avoid diplopia.

Constant squint, as its name implies, is always present, the visual axes never assuming normal relations. Opposed to it is *periodic* or *intermittent squint*, which is only present part of the time, the relations of the visual axes being at other times entirely normal. The periodicity may be looked upon as being an exaggeration of those variations in degree which constant squint usually presents; and it is irregular, not cyclical, unless dependent on some cyclical variation in the general nervous system, like that which attends menstruation.

Periodic squint is apt to be most marked when the general tone of the nervous system is low, or at times of great excitement, or when the eyes are particularly taxed; a form of convergent squint, appearing only during strong effort of the accommodation, being called *accommodative squint*. Squint occurring during violent disorder of the general nervous system would not be spoken of as periodic, but as *convulsive squint*. Closely allied to periodic and convulsive, perhaps standing rather between them, is *hysterical squint*.

Monolateral or *monocular squint* is the form in which it is always the same eye that fixes on the object looked at, while the other eye always deviates. If the fixing eye be covered it will deviate, while the ordinarily deviating eye fixes; but, upon uncovering, the deviation is soon transferred back to the eye which habitually presents it. The large majority of cases of concomitant strabismus are in this sense monolateral. But it must not be supposed that only the deviating eye is at fault. The squint is a faulty co-ordination of the motions of the two eyes, and the reason that it is always one eye that deviates is simply that the fixing eye has better vision, or is more easily used, as in hyperopia of differing degrees the use of the eye with the lower degree entails less exertion of the power of accommodation.

Alternating squint is the variety in which the deviation is sometimes presented by one eye, and sometimes by the other; either of them becoming the fixing eye when the other is covered, and continuing to fix after the other is again allowed to participate in the act of vision. Cases which are frequently at their outset, to some extent, alternating, may after a time become quite monolateral. Such cases, however, show from the start a disposition

to let one eye deviate more than the other; and true alternating strabismus may exist many years without tending to become monolateral, the determining factor being the equality or inequality of the two eyes as to acuteness of vision and ease with which they can be used.

Absence of Binocular Fusion.—In speaking of diplopia we have already given the conditions necessary for its production; and since, in the large majority of cases of concomitant squint, some of these conditions are lacking, most persons with squint do not experience double vision. In some cases it is quite obvious why there is no diplopia, as where corneal opacity, or a high degree of ametropia, prevents the formation of a retinal image in the deviating eye. In another class of cases the reason is less obvious, yet not hard to understand; as where, although the deviating eye presents no abnormal appearance either to external inspection or with the ophthalmoscope, when the ametropia is not excessive, yet the acuteness of vision is very low. Here amblyopia, probably indicating some defect of development, prevents the deviating eye from any considerable participation in the act of seeing. But there is still another class of cases in which, although each eye, when tested alone, shows good power of vision, and in which there can be no doubt that both eyes are usefully employed by their possessor, yet with marked squint there is no diplopia.

This state of affairs must be looked upon as a reversion to a type of visual act, common to most of the lower animals, in which, though they have two eyes, nothing like our binocular vision can be assumed to exist; the power of what has been called binocular fusion is lacking. It is quite conceivable that this power may now and then be lacking as a congenital anomaly; it may perhaps be always lacking at birth, and in all cases be a matter of individual development. Certainly it varies greatly in extent of development among those who undoubtedly possess it. The power is most developed and longest retained with reference to images formed on the macula lutea, if, indeed, it be not wholly confined to these. One who lacks entirely this power cannot have binocular diplopia, and cannot judge any better of the distance of unfamiliar objects with both eyes open than when one is shut.

Amblyopia with Squint.—Allusion has already been made to the large number of cases of squint in which there is great defect of vision, without any gross change to account for it. This amblyopia was formerly known as *amblyopia ex anopsia*, or amblyopia from disuse. It was supposed that squinting eyes presenting no lesion sufficient to account for their amblyopia had originally possessed good vision, that when they began to squint it caused diplopia, that to avoid diplopia the image formed in the deviating eye was actively "suppressed," excluded in some way from producing its proper effect on consciousness; and, further, it was supposed that this "suppression" or "exclusion" reacted injuriously on the sensibility of the eye subjected to it, causing a permanent amblyopia. For a time the frequent occurrence of this special form of amblyopia from disuse was scarcely questioned; but recently this series of suppositions has been challenged by various observers, most actively by Schweigger; and they have been shown to have no sufficient foundation in the facts. There is nothing to show that in many of these cases diplopia has ever existed. Where diplopia does exist in the beginning of a squint, it may disappear with the loss of binocular fusion, without the least impairment of visual acuteness; and in cases of paralytic squint, which are often seen from the beginning, and which sometimes become quite constant and are apt to be attended with very annoying diplopia, such a process as that supposed to lead to *amblyopia ex anopsia* is quite unknown.

Causes of Concomitant Squint.—The highly specialized character of the movements designed to secure binocular vision makes it extremely probable that they depend for their perfection on individual development. The controlling influence in such development is binocular fusion. Under the head of latent squint, we shall see how many cases of squint are kept from consummation by the desire to avoid diplopia, and it is in every way probable that a much larger number of cases are, during the early years of life, by this same impulse, led to so use the muscles which move the eyeball as to secure their symmetrical development and so do away with any tendency to squint. When, therefore, binocular fusion is impossible, or the tendency to it unusually feeble, as where the vision of one or both eyes is very imperfect, or where the faculty of fusion itself is not added to good vision of each eye alone, the orbital muscles never attain that normal development which enables them, by their elastic tension, to keep the visual axes properly directed to the point looked at. And while the rudiments of the proper binocular movements exist, so that both eyes may turn upward or downward, or to either side, at the same time, or converge somewhat more for near seeing, or somewhat less when a distant point is fixed, the perfection of their co-ordination, bringing the visual axes always to intersect at the point fixed, is not attained, and concomitant strabismus results. Of course, under this view anything which impairs the development of the visual centres or the acuteness of vision—as hereditary anomalies, convulsions, prolonged nutritive disorders, injury of the eyeball, keratitis, or high ametropia—becomes a cause of squint. But ametropia has an especial share in the causation of squint, as was first pointed out by Donders, although the importance of this factor has often been much exaggerated. Normally, the exertion of the power of accommodation is accompanied by convergence of the visual axes; the full power of the accommodation cannot be exerted without strong convergence. Hence in hyperopia, where the accommodation must be exerted more strongly to focus the image of the point looked at upon the retina, it is reasonable to expect a special tendency of the visual axes to converge more than in emmetropia, where the accommodation is less taxed. Statistics show that convergent strabismus usually occurs in hyperopic eyes. Still, as a large majority of all eyes present a low degree of hyperopia, it cannot be regarded as proved that the association of low hyperopia and squint is, in many cases, more than accidental. In the higher degrees of hyperopia, the proportion of patients presenting at least a periodic squint is too great to be accounted for in this way; and the view that hyperopia is, in some cases, one cause of squint, is fully supported by the results of treatment directed to the prevention of excessive effort of accommodation.

In myopia not only is it possible that the need for complete relaxation of the accommodation, even when a near object is looked at, may lead to deficient convergence of the visual axes, or divergent squint, but there is also an anatomical obstacle to normal binocular movements, in the shape of the myopic eyeball. The posterior segment of the emmetropic eye is spherical, and it rests in a spherical socket of orbital fat and connective tissue which it fits accurately, no matter in what direction the eye is turned. And in cases of hyperopia, even of the higher degrees, that are commonly met with, the deviation from the spherical form is comparatively slight. But in myopia, which runs into higher degrees than hyperopia, and of which the higher degrees are more common, there is an antero-posterior elongation of the globe which is often very marked. This makes the eyeball an oval, fitting in an oval socket, in which it cannot be turned without changing the shape or direction of the socket, by actual displacement of the orbital tissue. Hence convergence of the myopic eye requires excessive effort, while myopia, restricting the range of distinct vision, requires that the convergence should be especially great. Often, and in the highest degrees of myopia always, the effort at convergence is abandoned, and a divergent strabismus permitted. This is at first relative and periodic, but, if associated with deficiencies of muscular development, is very likely to become in time absolute and constant.

Treatment of Concomitant Squint.—The preventive treatment would include all measures favoring the normal development of the general nervous and muscular systems, or calculated to improve the acuteness of vision. Both to influence the acuteness of vision, and to give

the normal accommodation and range of distinct vision, *errors of refraction are to be corrected.* In convergent squint with hyperopia, the convex lens fully correcting the latter should be worn constantly. If the squint is commencing in a child too young to wear glasses, it is advisable to place the eyes under the influence of a *mydriatic*, as

Atropine sulphate	gr. j.
Distilled water	℥ ij.

one drop to be placed in each eye three times a day. This should be kept up for some time after the squint has disappeared, or, when squint continues, at least for some weeks, until it is clearly demonstrated that the deviation is not being favorably influenced by it.

The mydriatic acts by paralyzing the accommodation, and so preventing any attempt to use it which may bring about excess of convergence. This remedy is worth trying in any case of commencing convergent squint, whether associated with hyperopia or not. Care must be taken that the solution used is strong enough, and is efficiently applied; for if only enough of the mydriatic is instilled to somewhat weaken the accommodation, the effect will be not to prevent, but to increase the accommodative effort, and therefore the accompanying convergence.

In myopia concave lenses, either correcting all of it or so much as is necessary to enable the patient to see clearly at a distance of some twelve inches, may be used to prevent divergent squint. Or if the squint is already established, the use of correcting lenses, by making accommodation necessary for near vision, may bring about some convergence.

As aiding in the proper development of the muscles concerned, what are called *orthoptic* or *orthopædic exercises* are recommended. They consist usually in looking through some form of stereoscope at lines, letters, or figures, a part of each being seen by one eye, and the remainder being presented to the other eye; by an effort these are to be fused into one harmonious whole. An ingenious attempt in the same direction, proposed by Cuignet, is made by attaching to a firm head-band an arm projecting horizontally from the centre of the brow, from which are suspended the page to be looked at and a ruler placed vertically between the page and the eye. The ruler cuts off a part of the page from each eye, but by using both eyes all parts may be seen; and the reading of each line necessitates the alternate use of both eyes. Orthoptic exercises are mainly of use to cultivate the faculty of binocular fusion where that exists, but is deficient in comparison with the obstacles it has to overcome.

As a palliative of concomitant squint, prisms may be worn in rare instances. They are so used as to cause the rays to enter the squinting eye in the direction of its visual axis and thus avoid diplopia, while the squint remains unchanged. Or they may be used as a sort of orthoptic apparatus, to bring the rays so nearly in the direction of the visual axis of the deviating eye that, by a little additional effort, the visual axis will be brought to coincide with their direction, and the squint thus lessened. In either case the strength of prismatic effect required is to be determined by trial, and this secured by placing prisms of equal strength before both eyes, with the refracting angle or thin edge of the prism in the direction in which the eyes deviate. Thus, in a case of divergent strabismus a prism will be placed before each eye, with its edge toward the temple; in convergent strabismus, with its edge to the nose; or, if the right eye turns upward more than the left, a prism with the edge up before the right eye, or with the edge down before the left, will give relief. Because of the weight of strong prisms, the dispersion of light which they cause, and the apparent distortion of objects seen through them, it is scarcely practicable to wear prisms of more than from four to six degrees; and for this reason they are rarely useful in cases of actual squint.

Since in the vast majority of cases of squint it is impossible to so develop the muscles concerned that they shall, by their elastic tension and normal contraction, keep the visual axes in proper relation one to the other, recourse is had to *operative measures;* these are intended so to change the connection of these muscles to the eyeball that the visual axes may assume approximately their proper positions. These measures are two in number: One of them is the severing of the tendon of the muscle toward which the cornea is turned, allowing it to retract and the eyeball to be turned toward the proper position by its opponent, so that it shall attach itself farther back upon the sclerotic, and thenceforth have relatively less power to turn the eye in its direction; this is called *tenotomy of the rectus,* or *strabotomy.* The other is *advancement of the tendon* of the muscle which has exerted too little influence on the direction of the eye, allowing it to acquire a new insertion closer to the cornea, and so exert a relatively greater influence in determining the direction of the visual axis. Since operative procedure is only to be resorted to where development cannot be expected to accomplish the relief of the deformity, it should not be tried until development is so far advanced as to leave it clearly indicated. Thus, it should not be done before the age of six or eight years in the highest degrees of squint, until after puberty for moderate amounts, and for low degrees not until adult life is approached or reached. Again, it is wise, before operating for squint, to determine the refraction of the eyes and try the effect of correcting lenses upon the deviation, or, at least in the convergent form, to ascertain what effect is produced by the use of a mydriatic. Neglect of wise caution in this direction is responsible for the not rare conversion of convergent into divergent squint. It is not rare for squint to occur, sometimes to persist for months or even years, and then to spontaneously disappear; and the premature correction of such a case by operation, though perhaps quite satisfactory at the time, may in the end bring both operator and operation into discredit.

In determining the operation to be done the amount of deviation is to be considered. This may be measured in degrees on the arc of a perimeter, by placing the deviating eye at the centre of the arc, making the visual axis of the fixing eye parallel to the axis of the instrument, and noting the number of degrees from the axis of the perimeter to the visual axis of the deviating eye. Or, if convergent, the number of metre-angles of squint may be found by placing at the root of the nose a metre-measure graduated to metre-angles (the same as dioptric focal lengths), directing the fixing eye to the other end of the stick, and subtracting one from the number of metre-angles indicated for the point at which the visual axis of the deviating eye crosses the measure. Or the deviation can be measured by placing a scale along the edge of the lower lid of the squinting eye, covering the good eye so that the other may fix, and then uncovering it and watching the deviation. Where the deviation is slight it is usually to be corrected by a tenotomy; where the deviation is much greater than can be remedied by a single tenotomy, it is generally best to do an advancement; and, if this proves insufficient, a subsequent tenotomy may be resorted to. As a rule, the inward deviation that can be remedied by a tenotomy of the internal rectus is greater than the outward deviation that can be overcome by a tenotomy of the external rectus; and the effect of the former operation tends to increase for a certain time after its performance, while the effect of the latter rather tends to diminish.

To perform *tenotomy* of one of the recti muscles it is better to have an assistant, although the operation can be done without aid by using a spring-stop speculum to keep the eye open. The instruments required are a pair of scissors with fine but slightly blunt points, a pair of strabismus forceps (a form of fixation forceps with narrow toothed jaws), a strabismus hook, and a lid-elevator or speculum. A drop of a four per cent. solution of cocaine is to be placed over the insertion of the tendon to be cut. This is repeated every two minutes for five or ten minutes. The lid-elevator or retractor is then introduced beneath the upper lid and confided to the assistant, who stands behind the patient, steadying the head against his own

breast. The operator then seats himself on the same side of the patient as the eye to be operated on, and, with the forceps in one hand, seizes a fold of the conjunctiva some five mm. back from the margin of the cornea, and over the lower part of the tendon to be divided. With the scissors in the other hand, this fold in the conjunctiva is snipped so as to make an opening which, when stretched out, will be from five to eight mm. in length. The forceps are then allowed to drop the conjunctiva, and are introduced through the cut just completed and made to grasp the subconjunctival tissue. This is also divided with the scissors, and while it is still held by the forceps the points of the scissors are to be introduced beneath it, and, being alternately spread and brought together as they are pushed forward, are made to divide the tissue, until a free opening is obtained for the introduction of the hook. The scissors are then laid down and the hook is introduced, care being taken to keep the point in contact with the sclerotic, and is pushed back and then upward under the upper part of the tendon, which is drawn forward. The forceps are now removed and the hook depended upon to fix the eyeball. The points of the scissors are introduced beneath the conjunctiva, one point close to the hook beneath the tendon and close to its insertion, the other over the tendon and immediately beneath the conjunctiva. The blades being brought together, the tendon is divided and the hook can be pushed forward without hinderance to the margin of the cornea. The point of the hook is then turned downward, and the lower part of the tendon taken up and divided in a similar manner. When no bands remain to prevent the hook from freely slipping forward to the corneal margin, it is removed and the motility of the eye is tested. If motion is not decidedly limited in the direction of the cut tendon, the hook is to be introduced again and other bands searched for, especially at the upper and lower margins of the tendon, and these must all be divided, or no material effect will be produced by the operation. In this connection it is to be remembered that the width of the tendon to be divided is from six to ten mm. The effect of the operation can be considerably enhanced by freely dividing the subconjunctival tissue around the tendon.

For *advancement of the tendon* of one of the recti muscles, there are required, in addition to the instruments used for tenotomy, fine needles and silk sutures, and a needle-holder. It is better to have the patient recumbent, and, after the use of cocaine, the introduction of the elevator or speculum, and the tenotomy of the opposing muscle, an incision is made with the scissors in the conjunctiva, parallel to the corneal margin, five mm. from it, and extending the whole width of the tendon to be advanced, and some distance beyond it on either side. The tendon is now to be isolated and raised on the hook. A needle armed with the silk should then be passed through each margin of the tendon from without inward, some distance back from its insertion; and, having been drawn through, is to be introduced beneath the conjunctiva near the corresponding margin of the insertion, carried around the cornea, and brought out near the extremity of its vertical diameter, thus including a good mass of tissue. The ends of each suture are now tied together and the sutures drawn out of the way. The tendon is then severed at its insertion, and a small piece of it may be cut off if a decided change of the direction of the eyeball is desired. A third suture, connecting the centre of the tendon with the corresponding pericorneal tissue, is now introduced, and the sutures are tightened, care being taken that the upper and lower margins shall be equally drawn upon. The eye is then closed and bandaged. The stitches are allowed to remain several days, unless it is feared that too great an effect will be produced.

In a large proportion of cases, the *result* of operative interference is only an approximate correction of the deformity, which may sometimes be improved by the subsequent use of glasses, or orthoptic training. Only where good binocular fusion can be obtained may a perfect result be hoped for.

PARALYTIC SQUINT is a lagging behind of one eye when the patient attempts to look in a certain direction; it is due to limitation of the movement of the eye, by partial or complete loss of power in the muscle or muscles which should turn the eye in that direction.

Such palsies, like those of other muscles, may arise from lesions of the muscle itself, of the centres governing its action, or of the connecting nerve-tracts; usually they have the latter origin. Early, in a case of uncomplicated paralytic squint, all ocular movements which do not depend on the muscle or muscles affected may be perfectly normal; and, so long as no demand is made on these muscles, no diplopia or inconvenience results. But when it is attempted to turn the eyes in some direction where the action of the affected muscle will be essential, it is found that, while one eye responds normally to the impulse of the will, the other responds imperfectly or not at all; and the farther in this direction the sound eye is carried, the greater the deviation of the affected eye, and the wider the separation of the two images, which in this kind of squint are almost always present. Hence the squint and diplopia are not constant, but only appear when the eyes are turned in a certain direction—which sharply separates this from concomitant strabismus. In periodic concomitant squint the squint is sometimes absent, but when present it is so irrespective of the direction of the object fixed; in paralytic strabismus the squint, though sometimes absent, is always present when the eyes are turned in a certain direction, and always absent when they are turned in another. After paralysis of one of the muscles has existed for some time, its nutrition is impaired and elastic tension reduced, so that it is no longer sufficient to balance the elastic tension of its opponent. The latter turns the eye toward itself, so that it cannot assume the normal position, even when the muscles are relaxed as much as possible. When this occurs the deviation becomes more or less constant, and if some power of voluntary contraction be recovered by the paralyzed muscle, after its elastic tension has become thus impaired, the case assumes somewhat the character of a concomitant strabismus. The form of the squint depends on the muscle or muscles involved. It is, for practical purposes, convenient to classify paralytic strabismus by the nervous supply of the muscles involved.

Paralysis of the abducens nerve, or *external rectus muscle,* causes a most frequent and simple form of paralytic squint. The distribution of this nerve (the sixth cranial) being confined to the one muscle, and the action of this muscle being essential only to turning the eye outward (toward the temple), especially outward and upward (since the superior oblique has some power of turning it outward and downward), diplopia and deviation are only noticed when the patient tries to look toward the side on which the affected muscle is situated. If the paralysis be complete, diplopia begins as soon as the object fixed passes the median line; if it be but partial, it may not appear until the eyes have been directed somewhat toward the affected side. When the case has lasted some time, so that the internal rectus has acquired an elastic preponderance, the deviation and diplopia involve a greater part of the field of vision; but, in any case, the deviation and the separation of the double images are least when the eyes are directed most toward the sound side, and greatest when they are directed most toward the affected side. Congenital paralysis of both of the abducens nerves, causing a constant convergent squint with inability to turn the eyes to either side, without diplopia, and perhaps with excentric fixation, has been occasionally observed.

Paralysis of the Patheticus, Fourth Nerve; the Superior Oblique Muscle.—Here again we have a nerve supplying a single muscle, but one whose action is somewhat complex. Its function is to aid in turning the eye down and out, and to rotate it about the antero-posterior axis. The deviation and diplopia appear mainly when the eyes are turned toward the affected side and rather downward; when the eye is turned to the affected side the false image appears so inclined that its upper end is close to the upper end of the true image, while the lower deviates more widely from it.

Oculo-motor Paralysis.—The oculo-motor, or third nerve, which is distributed to three of the recti muscles—the inferior oblique, the elevator of the lid, and the iris and ciliary muscle—may be paralyzed in one or more of its branches. With the paralysis of its intra-ocular portion, causing loss of accommodation and some dilatation of the pupil, we are not here concerned. The involvement of all the extra-ocular branches causes drooping of the lid (ptosis), and leaves the eye unable to move in any direction except outward and a little downward, under the influence of the external rectus and superior oblique muscles. On attempting to look toward the sound side, or upward or far downward, deviation and diplopia appear, and increase *pari passu* with the effort to turn the visual axes in either of these directions. The same thing occurs when any attempt is made to converge for a near object. According to the movements attempted does the squint assume more the character of a divergent or a vertical strabismus.

When the sound eye is excluded from vision there is experienced a great uncertainty as to the position of objects, which amounts to a kind of vertigo. If the palsy has lasted more than a few days, a permanent outward deviation of the visual axis is usually established. Oculo-motor palsy may involve only a part of the muscles supplied by the nerve, or may even be limited to a single one. Almost always it affects some more severely than others ; and quite often, when all have been severely involved, some will recover almost completely, while others show little or no improvement. Hence, individual cases vary greatly as to the nature of the deviation and diplopia ; and each must be studied by the light of the general principles governing the occurrence of squint ; deviation occurs when the eye is turned toward the weakened muscle, and the false image is apparently displaced in the same direction. Several cases have been reported of oculo-motor paralysis recurring at considerable intervals, and tending to become fixed and associated with other cerebral symptoms ; the essential character of these paralyses is still unknown.

Ophthalmoplegia externa is the term applied to a paralysis of all the muscles attached to the eyeball.

Treatment of Paralytic Squint.—If the paralysis be due to some lesion, the location and nature of which are otherwise obvious, as a tumor, or is the result of some traumatism of the orbit, dependence is to be placed on the rational surgical treatment of the cause. Where, however, the palsy is the most definite or only symptom perceived, recourse must be had to internal or general medication. The largest number of these palsies come from some syphilitic new-growth, involving the sheath of the nerve or adjoining structures, or from syphilitic disease of the nerve itself. A few come from rheumatic disease in the course of the nerve-trunk, and a considerable number arise from a focus of disease in cerebro-spinal or spinal sclerosis. If there be a clear history of rheumatism, or collateral evidence of the rheumatic nature of the attack, anti-rheumatic remedies should be carefully tried. If there is other evidence of commencing or progressing sclerosis, we may assume this to be a manifestation of the general tendency in that direction. But in all other cases it is probably best to assume that the lesion is syphilitic, and to treat it with increasing doses of potassium iodide. A good way is to prescribe

Potassium iodide.................... ℥ j.
Water.............................. f ℥ j.,

each drop of which will contain about a grain of the drug. Let this be taken in water or milk, commencing with ten drops, three times a day. On the third day begin giving the same dose four times daily ; and after that, on each alternate day increase the dose by five drops ; and so continue until there is evidence of increase of power in the paralyzed muscles, or until symptoms of iodism appear. If decided improvement begins we may simply continue the administration of the drug without further increase of the dose, and if iodism occurs the drug must be suspended, or its dose considerably diminished.

In cases seen within a few days of the commencement this treatment generally secures great improvement, and not rarely complete recovery. But if many weeks or months have elapsed, there is not so much to be hoped from it. In very many cases, medical treatment leaves the cure far from complete, and certain local measures are to be resorted to.

It is scarcely practicable, on account of their situation, to pass through the affected muscles electric currents powerful enough to have much effect on them, without endangering the optic nerve and retina.

Prisms and tenotomy are not generally of any use, because the extent of the deviation varies with the direction in which it is desired to turn the eye. Where the paralysis remains absolute and the resulting deformity is very great, cosmetic improvement may sometimes be obtained by making an advancement of the tendon of the paralyzed muscle and the neighboring portion of the capsule of Tenon, with a tenotomy of the opponent muscle. The immediate effect, obtained in this way, should always be a decided deviation toward the paralyzed muscle, as the healthy opponent will, after a time, be sure to greatly lessen this effect. In cases of non-recovery or incomplete recovery from these palsies, passive motion, as proposed by Michel, has been used with apparent benefit to a considerable proportion of the cases subjected to it. Cocaine having been applied to the eye, the insertion of the paralyzed muscle is seized with the fixation forceps and the eyeball dragged back and forth in the direction in which the muscle would act, so that the muscle is alternately stretched and relaxed to its utmost ; and this is continued for about two minutes. This manipulation is to be repeated every two or three days ; but if no improvement is noticed after a few repetitions, none is to be hoped for from a further continuation of such treatment. When the cure of a case of paralytic squint is almost complete, orthoptic exercises may be of benefit.

Latent or Dynamic Squint.—A perfectly symmetrical development of the eye-muscles and their governing centres, which secures exactly the proper balance of elastic tension, contractile power, and motor impulse, that makes the co-ordination of binocular movements perfect, is perhaps as rare as is mathematically exact emmetropia. Binocular fusion is required to make up for its deficiency, in a very large proportion of cases, by inducing the slight extra, although involuntary, contraction of those muscles which without it fail to quite balance their opponents. In probably a large majority of persons the withdrawal of the influence of binocular fusion leaves a perceptible though slight squint. Such squint is called latent or dynamic, or is spoken of as an *insufficiency* of the weaker of the opposed muscles. It has also been proposed by Stevens to call it *heterophoria*, a tending of the visual axes toward different points. If not great, the latent deviation will cause no trouble to a person with a well-developed musculo-nervous system. But in persons of inferior muscular development and small reserve of nerve-force, even moderate degrees of insufficiency may give rise to the symptoms of eye-strain, especially if the eyes are required to do large amounts of work, or to work under unfavorable conditions.

Diagnosis of Latent Squint.—When, from the evidence of eye-strain, it is suspected that this form of strabismus is present, its existence is revealed by rendering impossible binocular fusion. For the objective test, binocular vision is rendered impossible by holding something opaque, as the hand, between one eye and the point fixed. The eye thus excluded will then, if there is the tendency to squint, be seen to deviate and take the position of equilibrium for the muscles that move it. Upon uncovering the eye, it quickly assumes again the position in which its visual axis will pass through the point fixed. In this way, by repeated trials and close watching of the eyes, quite low degrees of latent squint can be detected. But still more delicate is the subjective test. To make it, binocular fusion is prevented by placing before one eye a prism of about six degrees, with its base directly up. The eyes now being fixed upon some object, as a dot on a card across the room, this will appear doubled, the eye

with the prism before it seeing a false image below the true one. To make the test for a near point it is important to have the eyes accommodating for the point fixed, and to secure this the writer uses a single group of four fine crossed lines, like those shown in Fig. 3739, drawn on a plain card. If no tendency to squint be present, and the prism is held with its base directly up, the false image will be seen exactly under the true one, as represented in A, Fig. 3739; but if there be squint, the images will not be in the same vertical line, but in convergent squint will part from this position homonymously, and in divergent squint will be crossed. Thus, supposing the prism to be held with its base up before the right eye, the lower image will belong to the right eye, the upper to the left. An appearance like B, in Fig. 3739, will indicate convergent strabismus, the image of the right eye being to the right, and the image belonging to the left eye to the left. On the other hand, C, in the same figure, representing a tendency to crossed diplopia, indicates latent divergent squint. To determine the presence or absence of latent vertical squint, the most satisfactory test is the repeated trial of the power to "overcome" a prism with its base up, held first before one eye, then before the other. If any tendency to such deviation exists, it will be revealed by ability to overcome a prism with its base up before one eye, which cannot be overcome when the prism is placed in the same position before the other.

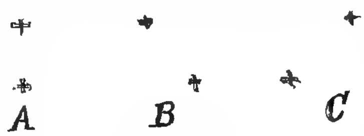

FIG. 3739.

Forms of Latent Squint.—Divergent squint, insufficiency of the internal recti muscles, or exophoria, is the most common. It was first described in connection with myopia, where it is particularly liable to cause trouble, on account of the need for unusually strong convergence; but it is even more frequent in persons who are hyperopic and use their eyes much, or under unfavorable conditions, for close work.

Convergent latent squint, insufficiency of the external recti, or esophoria, is frequently seen in hyperopes who tax their eyes. Vertical squint, insufficiency of the superior or inferior recti, or hyperphoria, is a very rare condition; but low degrees of it may cause much headache and nervous tension, because there is less power of compensatory extra contraction in the superior and inferior than in the lateral recti. A tendency to vertical deviation of more than from two to four degrees is too extensive a squint to be kept latent, and one even half as great may severely tax the reserve power of the muscles concerned.

Treatment.—All remedial measures spoken of in connection with other kinds of squint may be resorted to for this. On account of the lesser extent of the deviation prisms are particularly available. On the same account tenotomy and advancement require more accurate and delicate adjustment to the needs of the case, and are to be resorted to only after a thorough and rather prolonged acquaintance with those needs. But reduction of the amount of trying eye-work, and hygienic measures calculated to improve the condition of the nervous system generally, are of the utmost importance in the majority of such cases.

Mixed Forms of Squint.—While nearly all cases of strabismus are readily referred to one or the other of the foregoing classes, and while it is of the first importance to have clear conceptions as to the special characteristics of each class, it should not be forgotten that many cases present the peculiar features of more than one class. Thus we may have a dynamic divergent squint for distant vision running into an actual divergent squint for near work; or a case of well-marked concomitant squint with an overstretched muscle notably paretic; and allusion has already been made to the occurrence of concomitant in the later stages of paralytic squint. In strabismus, therefore, as elsewhere throughout the domain of medicine, each case is a subject for individual study, a most important kind of original investigation.

STRAMONIUM LEAVES AND SEED (*Stramonii Folia*, U. S. Ph., Br. Ph.; *Stramonii Semen*, U. S. Ph.; *Stramonii Semina*, Br. Ph.; *Folia Stramonii*, Ph. G.; *Stramoine ou Pomme épineuse*, Codex Med.; Jamestown Weed, Thorn-apple, Apple of Peru, Stinkweed, etc.). *Datura Stramonium* Linn.; Order, *Solanaceæ*.

FIG. 3740.—Flowering Branch of Datura Stramonium, with Fruit. (Baillon.)

This well-known weed is a coarse, smooth annual, from one to six feet high, with an upright tri- and dichotomously-branched stem, large ovate, coarsely dentate leaves, and long, bell-shaped flowers. The stem is stout, smooth, green (or reddish-brown, *D. Tatula*), more or less hollow; it branches at, say a foot from the ground, in three directions, and each of the divisions so formed soon forks repeatedly, the whole forming a spreading bushy head. Leaves alternate, lateral to the branches, petioled, ovate, pointed, irregularly and deeply dentate, with wavy margins. Flowers solitary, terminal, in the forks of the branches, short-peduncled. Calyx tubular, five-lobed, divisions pointed. Corolla funnel-shaped, three or four or more inches long, plicate and convolute in the bud. Border five-lobed, lobes pointed, pale pink, purple (in *D. Tatula*), or white. Stamens five, inserted in the tube of the corolla. Ovary two-, apparently four-celled; ovules

numerous. Fruit erect, ovoid, nearly as large as a hen's egg, covered with rigid sharp spines, opening part way down by four valves which curl back at the apex; seeds in four divisions, very numerous—"About one-sixth of an inch (4 millimetres) long, reniform, flattened, pitted, and wrinkled; testa dull brownish-black, hard, inclosing a cylindrical, curved embryo embedded in a whitish, oily albumen; of an unpleasant odor when bruised, and of an oily and bitter taste" (U. S. Ph.). The leaves, like those of belladonna, shrink very much in drying, and lose their peculiar nauseous odor. They are described as follows: "About six inches (15 centimetres) long, petiolate, smooth, ovate, pointed, unequal at the base, coarsely and sinuately toothed; after drying, thin, brittle, and nearly inodorous; taste unpleasant, bitter, and nauseous."

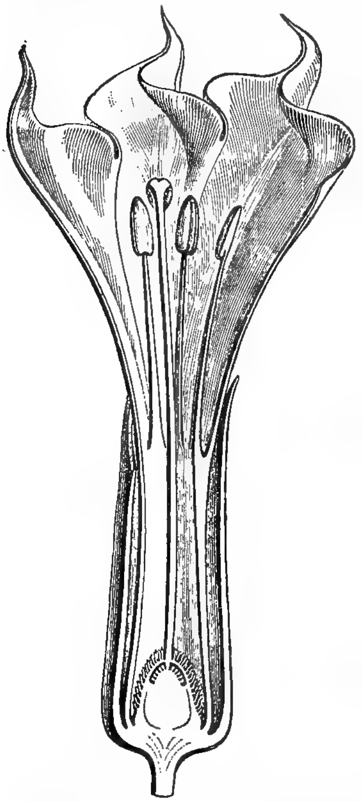

FIG. 3741.—Longitudinal Section of Flower of Datura Stramonium. (Baillon.)

The original home of Stramonium has been a puzzling question for botanists, apparently from the rapidity with which it spread over the earth in the sixteenth century. Tropical South America and the countries around the Caspian Sea are thought to be the most probable sources. It is more than possible that it is a native of both hemispheres. From whatever place it came, it has made itself at home everywhere over the warmer parts of the earth, taking most kindly to old rich gardens and corners, dunghills, and door-yards.

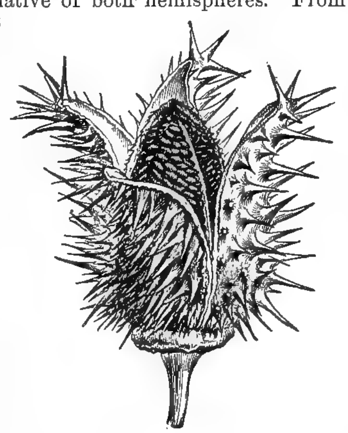

FIG. 3742.—Datura Stramonium; Ripe Fruit. (Baillon.)

COMPOSITION.—Stramonium contains the principal mydriatic alkaloids of the family: *atropine* and *hyoscyamine*—or at least the latter, and an amorphous alkaloid considered by Planta and others to be identical with the former, but either not fully proved to be so, or not yet prepared quite clean. *Daturine*, a name formerly given to the Stramonium alkaloids, is now said to be only hyoscyamine. The seeds contain about one-fourth of one per cent. of atropine, the leaves not more than one-third as much. Besides these the leaves contain a large amount of ash (14.5 per cent.), nitre, asparagin, and other unimportant substances.

ACTION AND USE.—From the above analysis it will be seen that Stramonium has scarcely any difference in action from Hyoscyamus, and but little from Belladonna. It is, indeed, capable of being used for exactly the same purposes, only it is more quieting and hypnotic than the latter, probably on account of its hyoscyamine. Custom, perhaps, as much as anything, has directed the leaves of this species, instead of those of the others named, to be used in the local antispasmodic treatment of asthma, for which purpose it is almost entirely prescribed. The common method is to administer it by smoking. The leaves may be burnt in a pipe or on the cover of a hot stove, or they may be made more inflammable by being soaked in a strong solution of saltpetre and dried, after which they will burn steadily, without flame and without requiring any apparatus; prepared in this way and flavored with aromatics and balsams, they are the foundation of most of the "asthma cigarettes" and "pastilles," which are often better products than extemporaneous preparations are apt to be. The French Codex gives directions for making cigarettes of stramonium, containing one gram each of leaves, without any admixture. For internal administration Stramonium may be considered the same as Hyoscyamus. The following preparations are officinal, all made from the seed, the leaves being only used for smoking (one or two grams): Extract (*Extractum Stramonii*), strength about $\frac{4}{1}$; Fluid Extract (*Extractum Stramonii Fluidum*), strength, $\frac{1}{1}$; Tincture (*Tinctura Stramonii*), strength, $\frac{1}{10}$; and the Ointment (*Unguentum Stramonii*), strength (of the extract), $\frac{1}{10}$. All these have similar properties and uses to the corresponding preparations of Hyoscyamus and Belladonna, but are more hypnotic than the latter. Dose of Fluid Extract about 0.2 c.c.

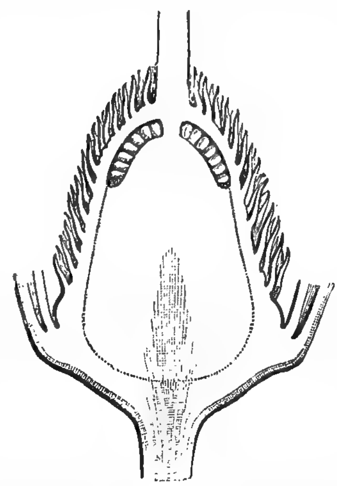

FIG. 3743.—Longitudinal Section of Ovary of Datura Stramonium. (Baillon.)

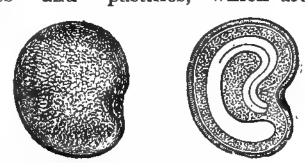

FIG. 3744.—Seed Entire and in Section, of Datura Stramonium.

ALLIED PLANTS.—*Datura*, of which the present plant is a characteristic species, consists of a dozen, mostly large, rank herbs, most of which have similar medical properties to the above. *D. Tatula*, with purple stems and flowers, is scarcely distinct from *D. Stramonium*. *D. alba*, of India, is used for the same purposes. One or two other species are cultivated for ornament. For the order, see BELLADONNA.

ALLIED DRUGS.—Belladonna, Hyoscyamus, Duboisia, Tobacco, etc. *W. P. Bolles.*

STRAWBERRIES (*Fraisier*, Codex Med., Rhizome, Fruit). *Fragaria vesca* Linn.; Order, *Rosaceæ*. The common garden Strawberry, like every other familiar plant, has been put to use as a medicine. Its leaves make by infusion a mild, rather pleasant, astringent tea, which is an occasional household prescription. With a little aromatic, like vanilla or ginger, a pleasant drink for those who cannot drink ordinary tea may be made.

Strawberry root, the rhizome and rootlets, dried, containing tannin, a little resin, etc., is an astringent and tonic of no great value, but is now and then employed as a domestic medicine.

Strawberries themselves have no medical properties, but the syrup made from them is an agreeable flavor for "siphon soda," and is frequently used by the sick for that purpose.

ALLIED PLANTS, ETC.—See ROSES. *W. P. Bolles.*

STRIBLING SPRINGS. *Location and Post-office,* Stribling Springs, Augusta County, Va.

ACCESS.—By the Chesapeake & Ohio Railway to Staunton, thence by stage thirteen miles to the Springs.

Springs Nos. 1 and 3 are chalybeate, No. 2 sulphur, and Nos. 4, 5, and 6 alum.

THERAPEUTIC PROPERTIES.—The variety and excellence of these waters render this a favorite resort. The alum springs are curative in chronic diarrhœa and catarrhs generally; the chalybeate are mild and efficient; and the sulphur is often needed to meet certain indications for which the others are not adapted.

These springs, sometimes called the Augusta, are located in the mountains of Eastern Virginia, and have long been popular, not only on account of the waters, but also for their beautiful and salubrious situation.

G. B. F.

STROPHANTHUS (Kombé, Arrow Poison, Inée, Onaye, etc.). The pods and seeds of several species of *Strophanthus;* Order, *Apocynaceæ.* This is a singular genus of tropical plants, mostly climbing shrubs. They are usually villous or hairy, although sometimes smooth, opposite-leaved plants with milky or colored bitter latex, terminal cymes of regular flowers, and very long fruits. Calyx five-pointed, glandular on the inside. Corolla funnel- or bell-shaped, gamosepalous, five-lobed, with ten scales or appendages; lobes pointed, in most species prolonged into long filiform or linear processes, six or eight times as long as the rest of the flower; these processes, whether erect, spreading, or, as sometimes is the case, straggling and drooping, serve at once to distinguish the genus. Anthers five, short, included in the corolla, upon which they are inserted by very short filaments. Pistil of two carpels, surmounted by one style and stigma. Ovules numerous. Fruit consists of two separate, diverging follicles, from ten to thirty centimetres long; they are fusiform, pointed, dehiscent; seeds numerous, from one-half to two centimetres long, silky or woolly, prolonged at the apex to a long, slender bristle, or awn, from five to twenty cm. long, which along its upper third, half, or more, becomes a plumose cylindrical brush. The genus comprises, according to Bentham and Hooker, eighteen species, all but one tropical, and growing in equatorial Africa, Southern Asia, or some of the Pacific islands; the extra-tropical species growing in Southern Africa. The Strophanthus seeds of commerce are probably the product of: 1, *S. hispidus* D. C., with hispid branches and leaves, and fine appressed tomentum upon the seeds; or of, 2, *S. Kombé* Oliver, a recently described species, perhaps scarcely distinct from the other, with coarsely hairy herbage and woolly seeds. Both these species inhabit Central and Western Equatorial Africa. There are, besides, several other species of the genus, with similar very bitter seeds, whose properties are probably similar to these, but so far they have not been tested.

DESCRIPTION.—Commercial Strophanthus pods are from twenty to thirty centimetres long, and two or three or more in breadth, slightly curved, longitudinally wrinkled, flattened, tapering to a fine point at the top. Color yellowish brown. They have a thin shell, finely grooved externally, and of a slightly brighter color inside.

The seeds are oval, flattened, tapering from near the base, about a centimetre long, four millimetres broad, and say two in thickness; a well-marked rib or keel on one side runs from the base to the apex; the awn is about ten centimetres long, plumed along the upper half with hairs whose length is three or four centimetres (the awn and their plumes are absent from the seeds as seen in the market). The surface of the seeds is densely silky, with shining hairs; it is grayish or greenish-brown, and is sometimes somewhat wrinkled lengthwise; section shows a whitish, oily kernel. The odor of Strophanthus seeds is bitter, and the taste (principally in the kernel) most intensely and disagreeably so. There are about two hundred seeds to each pod. All parts of the plant are bitter—seeds, pods, leaves, stems, and bark—but the seeds are by far the most so, and the most active, so that tinctures made of them alone, or of the entire pod, would differ much in strength. The hairs are inert.

HISTORY.—That certain tribes in the interior of Africa had efficient arrow poisons, and that some of these—inée, kombé, etc.,—were made in whole or partly from a paste made by grinding Strophanthus seeds, has been known for a number of years, and this poison was incidentally mentioned or examined by Pelikan, Hilton Fagge, and Stephenson in 1865, but the first serious investigation of its properties was published by Dr. Thomas P. Fraser in the "Proceedings of the Royal Society of Edinburgh," in 1870, who made an elaborate study of its action and chemistry, separating an active principle, of glucoside character in crystalline form, which he named strophanthin. (The strophanthin of the market at present is usually amorphous and rather deliquescent.) On account of the scarcity of the supply and other causes the investigations were not generally followed up, and for fifteen years the article was scarcely heard of, until 1885, when the same patient investigator read another important paper upon it before the British Medical Association, in which its utility as a medicine was shown by a series of cases and heart-tracings. Since this time it has been tried by numerous physicians in England and America, and so far, at least, with increasing reputation.

COMPOSITION.—The most abundant ingredient is a greenish fixed oil, of which about twenty-five per cent. can be obtained. This oil is slightly bitter, in consequence of the presence of a little of the bitter principle to be mentioned below, but is otherwise not remarkable or active. There is also a good deal of albuminous matter in the seeds, also inert. The active principle is *strophanthin,* a neutral glucoside, generally obtained as a light-colored, amorphous, moist powder, which is apt to deliquesce. As prepared by Mr. A. W. Gerrard (*Pharm. Journ. and Trans.,* May 14, 1887), it is "a pale-yellowish, amorphous substance, easily reduced to powder, but having some tendency to readhere. It is freely soluble in water and in alcohol, insoluble in pure ether and in pure chloroform; but if the latter liquids contain a trace of alcohol, a small portion of strophanthin is dissolved.

Strophanthin burns without a residue. It has well-marked glucocidal characters. He was unable to obtain it in crystals. One-fiftieth of a grain given to a dog proved fatal."[1] The crystalline strophanthin of Fraser does not appear as yet to be a commercial product. A crystalline substance can be obtained from the hairs of the seeds, called "*inein;*" it is not active. Gerrard's method of preparing strophanthin is as follows: An alcoholic extract of Strophanthus is dissolved in water, filtered, and precipitated with tannic acid. The precipitate is collected, washed with water, and while still moist mixed with an excess of basic acetate of lead. The mixture is dried, and exhausted with warm alcohol; the filtrate is treated with sulphuretted hydrogen, the sulphide of lead removed by filtering again, and the alcoholic solution evaporated to dryness. The residue (strophanthin) is dissolved in warm water, and then digested with animal charcoal, filtered, and evaporated.

ACTION AND USE.—Dr. Fraser, to whose extremely patient and scientific investigations we are indebted for the presentation of this new medicine, in his address before the section of Pharmacology and Therapeutics of the British Medical Society, 1885, says: "The pharmacological action of Strophanthus appears to be an extremely simple one. It may, I believe, be described in the few words that it is a muscle poison. However introduced into the body, it increases the contractile power of all striped muscles, and renders their contractions more complete and prolonged. In lethal doses it destroys, besides, the capacity of the muscle to assume the normal state of partial flaccidity, and causes the rigidity of contraction to become permanent and to pass into the rigor of death. As a result of the action on muscle, the heart is early and powerfully affected. It receives a larger quantity in a given time than any of the other muscles of the body, and therefore it probably is that Strophanthus affects its action more distinctly and powerfully than it does that of the other striped muscles. Indeed, by regulating the dose, a very distinct pharmacological influence may be produced upon the heart, while the other muscles remain apparently quite unaffected."

In order to ascertain the comparative effect of strophanthin and digitalin upon the heart muscle, Dr. Fraser exposed the separated heart of the frog to solutions of these substances. He found that "solutions of [Morson's ?] soluble digitalin of one part in a hundred thousand, of one in fifty thousand, of one in ten thousand, and of one in four thousand, each produced characteristic changes in the heart's action, but were not sufficiently strong to kill the heart, at any rate not within two hours. With strophanthin, on the other hand, a solution of one part in one hundred thousand quickly stopped the heart's action in extreme systole, characteristic changes in the heart's action having previously been produced. I then increased the dilution; and solutions of one part in two hundred and fifty thousand, of one in five hundred thousand, of one in a million, of one in two million, of one in three million, of one in four million and six hundred thousand, of one in six million, and of one in ten million, were each tried, with the result that the heart was characteristically affected, and killed by each of them. Even the almost inconceivably minute dose which was brought into contact with the heart, when a solution of one part of strophanthin in six million was used, produced complete stoppage of the heart's contractions in extreme systole in about twenty minutes." Its action upon the blood-vessels, on the other hand, was found to be less than one-tenth that of digitalis. Mr. Bahadhurji, who experimented with Strophanthus in co-operation with Dr. Langgaard in Berlin, found in frogs similar symptoms of heart-poisoning, with death in systole. Physiological doses reduced the number of beats to one-half, and made them more forcible; the heart filled well and emptied well. In rabbits very much the same thing was observed, the heart finally stopping in systole; the animal was sometimes convulsed before death. Strophanthus differs from digitalis in having a marked central effect upon the vagus. Blood-pressure tracings show no appreciable rise. Respirations at first increase, later are slower and weaker. Diuresis is not marked in healthy animals.

Dr. H. Hochaus, who experimented upon a number of persons, both well and suffering from several diseases, gives a careful résumé of the results in the *Deutsche medicinische Wochenschrift* of last year, of which the following is a synopsis, the doses for adults being from six to twelve drops of a five per cent. tincture of the seeds, say three times a day for several days, other circumstances of diet, etc., being the same:

In five cases of well persons, two showed no result, three increase of urine, two slowing of pulse.

In ten cases of valvular insufficiency, with soft, compressible, irregular pulse, and marked dyspnœa, two showed very great improvement, two moderate improvement, five no change. One improved remarkably, but died suddenly upon getting up. In some of the cases where Strophanthus failed digitalis was used with benefit.

In eighteen cases of enlarged, weak, myocarditic hearts, with diminished urine and weak irregular pulse, ten were more or less benefited and eight not improved; of the above ten who were benefited, six had been for several months in the hospital, and most of the different heart-strengthening medicines had been tried upon them. Digitalis acted best and quickest, next came Strophanthus.

In nineteen cases of nephritis, five of which were scarlatinous, one of these was much, one slightly benefited, three not at all. In one it produced diarrhœa. Of six cases of granular atrophy three were helped, and three were not. The remaining eight were cases of parenchymatous kidneys, with weak hearts, but little urine, and abundance of albumen. Of these three were improved in all respects, one in respiration only, and four not at all.

In two cases of pericarditis it did no good.

In two of chlorosis with functional palpitation it was beneficial.

From the above observations it will be seen that this drug is a very active one, that its effect upon the diseased heart is to strengthen its pulsations, and relieve numerous discomforts arising from its inefficiency, such as dyspnœa, palpitation, weakness, œdema, etc. It also in most of such cases increases the urine. It does not contract the vessels as digitalis does, and is said to be less likely to disturb the stomach; it is also not cumulative, the dose requiring to be increased after being used a while. On the other hand, it is claimed that it is less certain than the older remedy.

ADMINISTRATION.—The dose of Strophanthus cannot be considered as fully settled yet, but from one to six centigrams (from two-tenths to nine-tenths of a grain) of the seeds appears to be the usual range; it is not, however, given in substance, but usually as a tincture or a solution of strophanthin. No preparations are official, nor are they all uniform; therefore the physician should satisfy himself of their strength before using. Dr. Fraser's early tincture was about twelve per cent., which is stronger than is generally employed at present. His later recommendation is a five per cent. tincture, of which the dose is "from five to ten minims," and this strength is pretty commonly made now in this country. The directions for making are: "Strophanthus seeds, deprived of their comose appendages, reduced to powder, and dried, one ounce or part; ether, freed from spirit and from water, ten fluid ounces or ten fluid parts; rectified spirit, a sufficiency to obtain one (English) pint, or twenty fluid parts" (Fraser). The powder is carefully dried and exhausted of its fat by maceration and percolation with the ether, then redried and the tincture made in the usual way, by percolation with alcohol. Tincture of Strophanthus has a very pale straw color, and is intensely and nauseatingly bitter. The dose of strophanthin is variously stated at from .0003 to .001 gm. ($\frac{1}{200}$ grain to $\frac{1}{60}$.)

ALLIED PLANTS.—The common Oleander (*Nerium Oleander*) of the flower-garden is the nearest botanical relative at all familiar, the pods of the Oleander bear considerable resemblance to those of Strophanthus, and its

active principle, *oleandrin*, is also a heart poison. This may probably be said also of many plants in this poisonous order, see HEMP, CANADIAN, (*Apocynum Cannabinum*).

ALLIED DRUGS.—First, and most important of all, is Digitalis, which in its general usefulness probably exceeds Strophanthus, and to which the reader is referred (see FOXGLOVE); other heart "tonics" are Squills, Adonis, Lily of the Valley, and Antiaris.

BIBLIOGRAPHY.

The literature of Strophanthus is recent, and mostly consists of articles in magazines or in the proceedings of societies. The following references are to the most important articles:

STRYCHNINE AND NUX VOMICA, POISONING BY.

Probably the earliest mention of nux vomica in medical literature is that by the younger Serapion, an Arabian, who wrote toward the end of the tenth century (Ed. Argentorati, 1531, clxiii., p. 115). The earlier European writers who treat of the drug recognize its poisonous qualities (Wepfer, "Cic. Aquat.," Bas., 1679, p. 194; Hoffmann, "Syst. Med.," 1728, t. i., § vii.–ix.). So much were the earlier physicians impressed with the dangers attending the use of nux vomica that, notwithstanding the evidence of Fallopius, Sennert, and others, of its medicinal virtues, and its adoption into the Pharmacopœias of London, 1651, and Amsterdam, 1636, the opinion of Hoffmann: "Inter medicamenta suspecta et quæ virus quoddam reconditum alunt, ut adeo plus damni, quam utilitatis aliis expectandum sit, merito nux vomica referri debet" (Ed. Genev., i., p. 226) was that generally entertained.

The earliest medico-legal reference to nux vomica is by Valentine ("Corpus Juris Med. Leg.," 1722, p. 219), who in 1680 was called upon to recognize the poisonous character of nuces vomicæ seized upon a prisoner.

The discovery of strychnine by Pelletier and Caventou, in 1818, provided the medical profession with a potent remedial agent, but, at the same time, placed a formidable weapon in the hands of the poisoner and the suicide. Several years elapsed, however, before either medicinal or criminal use was made of the newly discovered alkaloid, although numerous experiments made upon animals by its discoverers and others, shortly after its first isolation, made clearly manifest the powers of strychnine.

Christison (second edition, 1832) states that, "except the hydrocyanic acid, no poison is endowed with such destructive energy as the strychnia." He also describes the effects of the alkaloid upon animals, but is completely silent concerning its action upon the human subject. Richter, in 1834 (Ex. Wibmer, p. 250) relates a case of dangerous, though not fatal, poisoning caused by the medicinal use of strychnine. Blumhardt (*Med. Corr. Bl. des Würt. Ver.*, 1837, i.) was probably the first to record the death of a human being caused by strychnine; a man, aged seventeen, who committed suicide by taking two scruples (!) of the alkaloid. Orfila (1852) cites three other cases, one suicidal (in 1846), the other two accidental (in 1849, 1850), by mistake for salicin and santonin.

The first instance in which justice was called upon to consider strychnine as a cause of death, was the classical Palmer case, which occurred in England in 1855, although it seems probable that the same defendant had previously poisoned his mother-in-law in 1848, and his wife in 1854, by the same agent. Shortly after the inquest in the Palmer case, and while the secular press was discussing the possibility of detecting strychnine, a second poisoning occurred in England (case of Dove), which affords a striking instance of imitative poisoning, and of the ill effects of popular discussions of such a subject.

The meagre statistics concerning deaths by poison in recent years, which are available through board of health reports, coroners' returns, etc., indicate that poisoning by strychnine is even now of rare occurrence. A comparison of reports of criminal trials shows, however, that, notwithstanding its intensely bitter taste, strychnine is used with homicidal intent more frequently than any poison, except arsenic. Of 146 cases which were the subjects of criminal trials, 47 were by arsenic; 23 by strychnine; 14 by hydrocyanic acid; 10 by mercurials; 7 by sulphuric acid; and the remainder by other poisons (five cases, or less, of each).

SYMPTOMS.—The symptoms of poisoning by strychnine or nux vomica are very characteristic.

If the dose be relatively small, although capable of causing death, there is at first an initiatory stage of nervous exaltation without any violent symptoms, whose duration varies inversely with the magnitude of the dose and the rapidity of absorption. The special senses are much more acute than normally, the mental functions are active, the patient is restless, and experiences a sensation of itching.

Soon twitchings of individual groups of muscles occur, followed by violent tetanic convulsions. During the spasms there is, in the great majority of cases, marked opisthotonos. The head is thrown sharply back, the body bent backward, the abdominal and thoracic muscles firmly contracted, the lower extremities rigid, and the soles of the feet bent inward and strongly arched. The lower jaw is fixed, the eyeballs protruded, the pupils dilated, the expression of the countenance distorted, the lips cyanotic, the mouth marked with froth—frequently bloody from the tongue being caught between the closing teeth—and the neck swollen. In some exceptional cases emprosthotonos or pleurotonos is observed instead of opisthotonos.

The spasm gradually passes off, the muscles relax, the eyes and pupils become normal, and respiration is resumed. The patient speaks, usually calls for air, desires to be held, and is in dread of impending death. Indeed, consciousness and intellectual activity do not seem to be impaired during the spasms.

After the first convulsion others, similar in character, occur, either spontaneously or in consequence of very slight *unexpected* excitation. An attempt to move the patient, a slight jarring of the floor or bed, a sudden noise, a slight draught of air, or even a flash of light, is

sufficient to provoke a spasm if the patient do not expect it. On the other hand, much more active excitation fails to call forth a spasm if the patient be not taken unawares; and he frequently asks to be rubbed, held down, or moved. When the spasm recurs spontaneously, the patient usually announces its coming some seconds in advance, and asks to be held.

The number of convulsions varies from three to ten; their duration from thirty seconds to five or even eight minutes. The intervals vary in duration from forty-five seconds to one hour, or even one and a half hour; usually five to fifteen minutes.

In cases terminating in recovery the interval between the spasms increases in length, and the convulsions become less active and shorter in duration, and finally cease, leaving the patient in a condition of great muscular fatigue, and with increased reflex irritability. In fatal cases death results from one of two causes: In some cases death is due to asphyxia by fixation of the muscles of respiration during a protracted spasm; in others it is due to exhaustion, and occurs during the non-tetanic period. In most fatal cases death occurs during or after the fourth or fifth tetanic seizure, although cases have occurred in which the patient has succumbed at a later period, and others in which life was extinguished during the third, second, and first convulsion.

Duration.—The rapidity of action of strychnine is modified by the form in which it is taken, whether in solution or in a hard and difficultly soluble pill, and by the length of time which is allowed to elapse before treatment is resorted to.

In 49 cases, in which the time of first appearance of the symptoms was noted, the period was "directly, or very soon," in 12; from three to thirty minutes in 22; from thirty minutes to one hour in 7; from one to two hours in 6; and two and a half and three hours in 2. The average period of delay is, therefore, within twenty minutes. The extremes are "directly" and three hours.

The total duration of strychnine poisoning is also short, whether it terminate in death or in recovery. Of 40 fatal cases of which the duration is stated, 20 died within one hour; 8 in from one to two hours; 7 in from two to three hours; and 5 in from five to six and a half hours. In the majority of these cases the entire duration was less than one hour. The extremes were "immediately" (from a dose of one and three-fourths grain, combined with an equal quantity of nux vomica), and six and half hours (from a dose of three grains), both adult males.

The time elapsing between the beginning of symptoms and death has varied in 21 cases as follows: 8 within thirty minutes; 6 in from half an hour to an hour; 4 in from one to two hours; 3 in from two to five hours. The extremes are five minutes (male, aged twenty-six; dose five grains; symptoms began in fifteen minutes), and five and a quarter hours (male adult; dose three grains; symptoms began in forty-five minutes).

In non-fatal cases recovery is usually rapid, the active symptoms cease within a few hours, and, after cessation of the spasms, the patient may be considered as out of danger, although in exceptional cases great muscular prostration and occasional involuntary muscular contractions continue for some days.

Differential Diagnosis.—The disease bearing the closest resemblance to strychnine poisoning is tetanus, whether traumatic or idiopathic. In poisoning by strychnine the attack is more sudden than in tetanus, and the entire history of the case is compassed within a few hours, in place of lasting for days. The spasms follow each other at shorter intervals, and are of less duration, in strychnine poisoning than in tetanus. In the latter, trismus is one of the earliest and most prominent of the characters, while in the former it occurs later, if any succession of symptoms be observable, and may be insignificant as compared with the violent tetanic contraction of the respiratory muscles. During the intervals between the convulsions due to strychnine the muscles are usually relaxed, while in tetanus they remain more or less rigid, particularly those of the lower jaw. The chief points of distinction are in the much more rapid progress of strychnine poisoning, and, in the great majority of cases, in the history of the onset, which, in the poisoning, follows, with very little warning, within two hours or less, the ingestion of some bitter substance, but in tetanus is gradually developed several hours or days after an injury.

Uncertainty concerning the diagnosis between epilepsy and strychnine poisoning can only occur in the very exceptional case of an unknown person dying during a single convulsion. In such an event chemical analysis would decide the question definitely. In other cases the history of the case, the much longer interval between the paroxysms in epilepsy, and the more distinctly tonic character of the spasms in strychnine poisoning, are sufficient to establish the distinction.

In cases of poisoning of pregnant women by strychnine (two such are cited by Wharton and Stillé, pp. 443, 625), the distinctions between the effects of the poison and puerperal convulsions are of importance. The principal diagnostic point is in the fact that in puerperal convulsions the patient is entirely unconscious of what occurs, either during or between the convulsions, while in strychnine poisoning consciousness remains unimpaired, except immediately before death. The detection or non-detection of strychnine in the body would remove all doubts.

Lethal Dose.—The smallest amount of strychnine which has been known to cause the death of an adult is 0.016 gram (= ¼ grain), which produced violent symptoms in ten minutes in a female, aged thirty-six, and death in one hour and forty-five minutes (*Medical Times and Gazette*, 1854, p. 376). Double this quantity, 0.032 gram (= ½ grain), caused death in two cases. In one of these (case of Dr. Warner) a physician took by mistake half a grain of the sulphate, was violently convulsed in five minutes, and died in twenty minutes. Less quantities have produced dangerous poisoning in adults. Christison cites the case of a child of three years, which was killed in four hours by 0.004 gram (= $\frac{1}{16}$ grain).

On the other hand, numerous cases are on record in which much larger doses have been taken without causing death. Thus Campbell (*Lancet*, 1856, ii., 695) relates a case in which a man, aged thirty, took 0.65 gram (= 10 grains) of strychnine and recovered. Shaw (*American Journal of the Medical Sciences*, 1856, 547) cites the case of an adult female who recovered from the effects of a dose of 0.65 to 0.97 gram (= 10 to 15 grains). Tschepke (*Deut. Klin.*, 1861, ex "Maschka Handb.," ii., 613) gives a case of a pharmacist who took from 0.48 to 0.72 gram (= 7½ to 11 grains) of strychnium nitrate dissolved in about 30 grams (= fl ℥ j.) of bitter almond water, and, after half an hour, having experienced no symptoms, 0.6 gram (= 9¼ grains) of morphium acetate, also dissolved in bitter almond water. Subsequently, being still capable of locomotion, he poured chloroform upon his pillow and lay with his face upon it. An hour and a quarter after taking the first dose he suffered violent symptoms of strychnine poisoning, from which he, however, recovered under treatment by emetics and tannin. Atlee (*Medical Times and Gazette*, 1871, p. 283, ex *Boston Medical Journal*) cites a case in which the amount taken was probably the largest not causing death. The amount taken was 1.30 gram (= 20 grains), immediately after a meal. Emesis was provoked very soon after.

Treatment.—The ends to be aimed at are, first, the removal of any unabsorbed poison from the stomach, if possible, and, second, the prevention or mitigation of the paroxysms. For the attainment of the former an emetic of zinc sulphate or of apomorphine should be given, if the case be seen early, followed by tannin, with the view of converting any remaining strychnine into an insoluble compound. Chloral should be generously administered, followed by inhalations of chloroform sufficient, and sufficiently prolonged, to control the convulsions until the poison shall have been eliminated, as it is with considerable rapidity. In the exceptional cases in which the patient is seen before the tetanizing action of the poison has been established, the stomach should be washed out as expeditiously as possible with a strong infusion of tea, or a solution of tannin in some form, or water holding

powdered charcoal in suspension. No reliance is to be placed upon camphor, albumen, opium, aconite, cannabis indica, or tobacco, which have been suggested as so-called physiological antidotes.

Post-mortem Appearances.—There are no peculiarities discoverable, on external or internal examination, which are characteristic of this form of poisoning. Rigor mortis is more rapidly established and continues for a longer period in most cases. According to Wharton and Stillé, rigor mortis was very marked in the body of a woman exhumed two weeks after death (*Medical Jurisprudence*, ii., 445). Taylor ("Poisons," third American edition, 676) states that cadaveric rigidity was well marked in the body of Cook two months after death. Usually the body is relaxed at death and soon stiffens, but in some cases the tetanic spasm merges into rigor mortis. But instances are met with in which cadaveric rigidity has disappeared in from twenty-four to forty-eight hours. In some cases the hands are firmly clenched and the soles arched after the other muscles have become relaxed. Rigidity is of shorter duration in the bodies of those in whom the spasms have been more or less controlled by treatment during life, than in those who have died without medical interference. The surface is usually livid, but not in all cases. Sometimes lividity is confined to the fingers, and in some cases the inner surfaces of the thighs and arms assume a red color.

The internal appearances are still less characteristic. The blood is usually fluid, and dark. The vessels of the scalp, the brain and its coverings, and of the spinal cord, as well as the lungs, are in most cases congested. The heart is usually empty and sometimes firmly contracted, the right side being less so than the left, and sometimes distended with dark, fluid blood. The bladder is usually empty, though in some cases it has been found to be nearly full of urine. Occasionally ecchymotic spots or patches of congestion are observed in the stomach.

Analysis.—In cases in which the analysis is not to be limited to a search for strychnine, the systematic method of Dragendorff for the separation of alkaloids and glucosides from organic mixtures (see Vol. V., p. 764) should be followed. By this method any strychnine which may be present in the substances examined will be found in the residues of evaporation of the petroleum-ether and benzol extracts from the alkaline aqueous solution.

In all cases it is advisable to resort to Dragendorff's method, even when the history of the case points very directly to strychnine, as any question subsequently arising as to the presence or absence of another alkaloidal or glucosidal poison can then be determined.

In some exceptional chemico-legal cases, and when the physician wishes to determine the presence or absence of strychnine in the urine during the life of the patient, an abridged modification may be used. If the substances to be examined be solid, they should be finely divided and placed in a flask, to which water, rendered distinctly acid with sulphuric acid, is added in sufficient quantity to cover the solid. After agitation, the reaction of the liquid is to be determined, and if not distinctly acid, it is to be rendered so by the addition of dilute sulphuric acid. The flask and its contents are then to be placed in an oven heated to 40°–50° C. for six or eight hours, after which the liquid is to be filtered off. A fresh portion of dilute acid is to be added and the extraction repeated four or five times. The united acid filtrates, which contain any strychnine that may be present in the form of the sulphate, are then evaporated to the consistency of a thin syrup over the water-bath. The residue is mixed with four volumes of strong alcohol, gradually added during stirring, and allowed to macerate twenty-four hours. The alcoholic liquid is filtered off, the residue on the filter washed with strong alcohol, and the filtrates and washings evaporated over the water-bath until free of alcohol. The residue, thinned with water if necessary, is transferred to a stoppered cylinder. The solution should not exceed 100 cc. in bulk, and may be less. About 50 cc. of benzol (boiling-point not over 85° C.) are then added and the cylinder strongly agitated once every five minutes for about half an hour. The benzol layer is then removed by the separatory funnel and a fresh portion added to the aqueous liquid, which has been returned to the cylinder. This extraction of the acid aqueous liquid is repeated (usually four or five times) until the benzol no longer leaves a residue on evaporation. The purpose of this extraction is to remove pigmentary and other substances, whose presence materially interferes with the reactions. The aqueous liquid is now rendered distinctly alkaline with ammonium hydrate, and again repeatedly extracted with benzol as described above, but the benzol layers now separated are evaporated in several watch-glasses, and it is to the residues so obtained that the tests for strychnine are to be applied.

If the substance to be examined be a liquid, it should either be evaporated to dryness, the residue extracted with acidulated water, and the filtered aqueous extract treated with benzol, the watery solution being first acid, then alkaline, as above described; or, in the case of a simple aqueous solution, the treatment with benzol may be applied directly, care being had as to the reaction.

In order that the tests may be relied upon, particularly when the alkaloid is present in small amount, as in the case of absorbed strychnine, it is essential that foreign substances be removed as completely as possible. Therefore, if the benzol residue from the alkaline solution be colored, it should be purified by dissolving it in a small quantity of dilute sulphuric acid, agitating with benzol, rendering alkaline, and again extracting with benzol.

Tests.—1. The crystalline form was formerly much relied upon. Strychnine crystallizes from an alcoholic solution in small, four-sided, orthorhombic prisms, terminating in four-sided pyramids; sometimes also in small hexagonal plates. Precipitated by ammonia from solutions of its salts, it forms slender, needle-like, four-sided prisms. As, however, many other substances crystallize in the same form, and as, when the alkaloid is present in very small amount and other substances are present, or when the solvent is rapidly evaporated, the form of the crystals may be modified, or they may not be produced at all, the presence or absence of crystals can only be considered as confirmatory evidence.

2. The taste of strychnine is intensely and persistently bitter, with a faintly metallic after-taste. The bitter taste is still perceptible in a solution containing only one part of strychnine in six hundred thousand of water. The value of this quality is simply confirmatory, as there are many substances other than strychnine whose taste is bitter.

3. Strychnine dissolves in concentrated sulphuric acid, forming a colorless solution of the sulphate. If, now, nascent oxygen be generated in the solution, a peculiar play of colors is produced; at first, and but for an instant, blue (this is sometimes absent), then violet, which gradually changes to red, and then to yellow.

This test, which is most delicate and characteristic, may be applied in a variety of ways.

The sulphuric-acid solution may be placed upon a strip of platinum foil connected with the positive (platinum) pole of a single Grove cell, and a platinum wire, connected with the negative (zinc) pole, brought into contact with the upper surface of the drop of liquid. The nascent oxygen liberated at the foil produces a purple-violet blotch.

The sulphuric-acid solution may be placed in a watch-glass upon a white background, and a minute fragment of some solid substance capable of yielding oxygen by contact with sulphuric acid drawn through it with a stirring rod. The path of the solid is marked by a streak of color passing through the shades above mentioned. Either black oxide of manganese, oxide of cerium, permanganate of potassium, dichromate of potassium, ferricyanide of potassium, or peroxide of lead may be used. Black oxide of manganese and dichromate of potassium are preferable to the other substances mentioned, and both should be used with separate portions of the residue, if there be sufficient. The dichromate acts quite rapidly, the blue color is not produced, and in solutions containing no strychnine only a yellow color is communicated to the liquid. The oxide of manganese acts much more

slowly by reason of its less solubility, the blue color is developed, and, in the absence of strychnine, the liquid remains colorless.

The only substance producing a similar play of colors under like treatment is curarine, the alkaloid of the South American arrow poison. But the change of colors with that alkaloid takes place much more slowly than with strychnine. Curarine is, moreover, colored red by sulphuric acid alone, while strychnine forms a colorless solution with the acid. Any possibility of error is avoided if the method of separation above described have been followed, because curarine is not extracted from either acid or alkaline aqueous solution by petroleum-ether or benzol, but remains in the aqueous liquid.

Aniline also gives a blue-violet color with potassium dichromate and dilute sulphuric acid, but this color does not change to red and yellow, but to black; while a peculiar odor, somewhat resembling that of bitter almonds, is given off, which is not observed in the case of strychnine.

The reaction is interfered with to a greater or less degree by the presence of sugar, morphine, or other reducing agents, brucine, and other substances; therefore the foreign bodies should be removed as completely as possible before the test is applied.

This color reaction is distinct with $\frac{1}{600000}$ grain of strychnine.

4. The physiological test, first suggested by Marshall Hall, is also extremely delicate. A small frog is well dried and held by the hind legs, the skin of the back over the coccyx is raised by a pair of forceps, and a small incision made through the skin into the lymph-pouch with a pair of pointed scissors. A few drops of the solution under examination are then allowed to flow from a pipette into the lymph-pouch, and the animal is placed under a glass shade. If the liquid contain strychnine the animal becomes uneasy in about ten minutes; the respiration is accelerated; and violent tetanic convulsions are provoked by striking upon the table, by blowing upon the animal, or by other slight irritations.

5. A solution of iodic acid in concentrated sulphuric acid colors strychnine brick-red, the color changing to violet.

6. Solution of potassium dichromate causes a yellow, crystalline precipitate in solutions of strychnine or of its salts. If this precipitate be moistened with sulphuric acid, the play of colors described in 3 is produced.

Other reactions of strychnine are the following: With solutions of the alkalies, or alkaline carbonates, a crystalline precipitate of strychnine from moderately concentrated solutions of its salts. With tincture of iodine, or solution of iodine in potassium iodide solution, a dark red-brown precipitate. With platinic chloride and with auric chloride, light-yellow precipitates, gradually becoming crystalline. With potassium-iridium chloride, a dark-brown precipitate, which disappears on agitation, but gradually reappears in the form of crystals. With potassium platinocyanide, a white, crystalline precipitate. With potassium-cadmium iodide, a white, flocculent precipitate. With potassium iodhydrargyrate, a fine, white precipitate. With phosphomolybdic acid, a yellowish-white precipitate. With picric acid, a yellow precipitate, which gradually becomes crystalline. With tannic acid, an abundant, white precipitate.

Failure of Detection.—The reactions of strychnine are clearly defined, and it is difficult to suppose a case of death from the effects of this poison in which a properly conducted analysis would not reveal the presence of the alkaloid in the cadaver. It is unquestionable that death may result from the action of certain corrosives and poisons, without any trace of the substance remaining in the body after death. In cases in which a mineral acid or alkali destroys life by starvation, weeks or months after the corrosive has been taken, and in cases of death from digitalis, on the fifth or sixth day, the agent which was the remote cause of death has been eliminated before the fatal termination, and consequently will not be detectable by analysis. The duration of a fatal case of strychnine-poisoning is, however, so short (the maximum lapse of time being six and a half hours, and the average less than one hour from the taking of the poison) that it is, to say the least, highly improbable that a person should die from the effects of this poison and no trace of it remain in the body.

Yet cases have occurred in which death has been undoubtedly due to strychnine, and an analysis has nevertheless failed to reveal the presence of the alkaloid in the cadaver. An historical instance is the case of Palmer, tried in London in 1856, in which Professor Taylor, who made the analysis, did not obtain chemical evidence of the presence of strychnine, although the deceased, Cook, was seized with violent tetanic convulsions fifty-five minutes after taking the poison, and died in about fifteen minutes thereafter. The failure of this analysis (for such it must be considered, as complete elimination in so short a time is not possible) was the subject of much bitter controversy, and seems to have permanently warped the mind of Dr. Taylor on the subject of chemico-legal evidence. It was due to two causes, both avoidable. The autopsy was conducted without the commonest precautions necessary in such cases. The defendant was present, and accidentally (?) caused the loss of the contents of the stomach; and the solid viscera were only obtained for analysis at a later date. But the loss of the contents of the stomach, although they probably contained strychnine in larger quantity than the tissues, would not have caused complete failure of the analysis had the analytical processes been properly conducted. In a case of compound poisoning by arsenic and strychnine, in which the analysis was made by the author in conjunction with Professor C. A. Doremus, no evidences of the presence of the alkaloid were obtained with the residues (by the Dragendorff method) first obtained, but on suitably purifying these residues, positive reactions were observed in the contents of the stomach, those of the intestines, and in the liver, kidneys, and heart.

When the amount of strychnine present is large, positive reactions may be obtained even in the unpurified residues; but when the amount is small, as it must necessarily be when absorbed, it is imperative that the alkaloid be freed from other substances as completely as possible before the tests are applied.

Influence of Putrefaction.—Strychnine is one of the most stable of the alkaloids, and remains unaltered in contact with putrefying animal substances for a long time. Cloetta obtained distinct reactions from viscera containing strychnine which had been buried three, six, and eleven and a half months (*Arch. f. Path. Anat.*, Bd. xxv., p. 369). Rieckher (*Zeitsch. f. Anal. Chem.*, vii., 400) demonstrated the presence of strychnine in a mass of heart, lung, and liver exposed to the ordinary variations of temperature, with which it had been mixed eleven years previously. *R. A. Witthaus.*

STUTTERING. Stuttering is a functional speech defect, consisting of clonic or tonic spasm of the muscles of respiration, phonation, and articulation, induced by the attempt to utter articulate sounds.

The intensity of the spasm varies greatly in different cases, from a scarcely noticeable impediment in speaking, to an attack which renders speech for the moment impossible. The disturbance results in closure of the air-passages, which is with difficulty overcome by the patient, and usually occurs in connection with the explosive consonants, in producing which there is normally a closure either by the lips, by the tongue, or by the soft palate. It may, however, occur with the pure open sounds, or before a sound has been uttered, in which case the spasm originates at the glottis. There may or may not be a repetition of the offending sound, but there is apt to be when it is one of the explosives.

The attacks occur irregularly, and are much influenced by circumstances. Thus a stutterer may be able to converse easily with his friends, but be unable to bring out a syllable when talking with strangers. Or he may be able to carry on an ordinary conversation, but have trouble in telling a story, or making any prolonged effort at speech. One may stutter only when tired or slightly out

of health. Stutterers are usually exempt when whispering or singing, but this rule has frequent exceptions.

Stuttering has been known from the earliest times, but has been generally confused with other speech defects, so that it is often impossible to tell whether an account relates to this, or to aphasia, or to stammering. It differs from the latter in origin, is never due to organic defect, nor entirely to carelessness, is intensified when the patient's attention is directed to his speech, or when he is embarrassed, and it is only occasional, while stammering is regular. Under favorable circumstances the stutterer's enunciation is perfect. It is evident, then, that it is no mere defect of articulation, nor of co-ordination, for the muscles at times harmonize perfectly in their action.

Stuttering is mentioned by Hippocrates, Aristotle, and Galen, but in a somewhat indefinite way. We are told by Plutarch that Demosthenes had a difficulty of enunciation, which he overcame by declaiming as he walked up hill, and by holding pebbles in his mouth as he rehearsed his speeches. The latter plan has points of resemblance with modern devices, as we shall see ; but it is not at all certain, from the account, whether the defect which it removed was really a stutter, or some form of stammer. At any rate, he adopted an excellent form of respiratory gymnastics, which are the foundation of most of the modern systems of treatment.

During the Middle Ages, writings on the subject appeared occasionally, imputing the trouble to malformation of the tongue, cerebral disease, etc., but no work of importance was done until the beginning of the present century.

Itard (1817) divided stuttering into two classes, congenital and accidental. Under the latter head he included all speech defects due to cerebral lesion or organic disease of the tongue. It will be seen that this included what is now known as aphasia. In the congenital form he considered weakness of the organs of articulation as accompanying, not causing, the difficulty. He recommends beginning treatment early, and teaching the child slowly and carefully the pronunciation of a foreign language, dropping for a time its own. In this way he is taught, from the very first, to combine sounds properly, and to give prominence to the vowel sounds rather than to the consonants.

In 1825, Mrs. Leigh, of New York, discovered a method of treatment which was kept for a long time secret. Her observations were made on the daughter of a physician in whose house she was governess, and she afterward established an institute for the cure of stutterers. She thought the trouble due to a faulty position of the tongue, which is spasmodically depressed during the attack. To overcome this, she taught her patients to voluntarily raise the tip of the tongue, and keep it in this position while speaking. Her results were at first surprisingly good, and attracted a good deal of attention, as well throughout Europe as in this country.

Malebouche bought Mrs. Leigh's secret, and carried it to Europe. He attempted to improve on it, but only succeeded in altering it in minor details. He taught the system in Brussels, and finally sold it to the Prussian Government, who went so far as to appoint a professor of it. It was reported on by Magendie in a communication to the French Academy. He thought its value only temporary.

In 1826, McCormack, unable to learn Mrs. Leigh's secret, set to work to discover it for himself. He arrived, however, at a different conclusion, namely, that the trouble is one solely of respiration, and that it is only necessary for the stutterer to fill his lungs well with air before each sentence.

M. Serres d'Alais (1829) published a more scientific résumé of the subject, in which he divided the cases into two classes :

1. Those due to a stiffness, as if tetanic in character, of the muscles of the voice and respiration.

2. Those due to a chorea of the muscles of articulation. He recommended in severe cases gymnastic movements of the arms while speaking; in light cases he considered it sufficient to pronounce the syllables in a short and brusque way, at the same time making the movements of articulation as extended as possible. He admitted that recovery is never quite complete, differing in this respect from most writers of the time, who, skeptical as to the statistics of others, claimed infallible results from their own particular method of treatment.

Chégoin (1830) anticipated by some years the rage for operation which was afterward to sweep through Europe. He thought the trouble entirely due to malformations of the tongue, consisting in either a real shortness of the tongue or a faulty position of the frænum, which then binds the tongue too tightly to the floor of the mouth. He recommended cutting the frænum, but thought the operation beneficial only when performed early, soon after the child has begun to talk. For shortness of the tongue he thought a silver plate on the teeth might be of service.

Arnolt (1830) ascribed the difficulty to spasmodic closure of the glottis. To overcome this he caused his patients to make a *ŭ* sound between the words, so as to bind the consonant rather with the preceding than with the following vowel sound. In this way he threw the consonant sounds into the background, as one does in singing.

At about this time Colombat, in France, attracted a good deal of attention by his brilliant success in treatment. He claimed to have cured one case in a single sitting of three hours, but, in a later edition of his work, considerably modified this statement, and other authorities say the case relapsed several times. In fact, so many tables of statistics have been compiled from the immediate results of treatment, without waiting to see whether relapse occurred, that they are almost entirely worthless. Colombat gives a classification of cases much like that of Serres d'Alais, into :

1. Repetition of syllables due to convulsive movements of the tongue and lips, or labio-choreic form.

2. Tetanic stiffness of the muscles of respiration, or gutturo-tetanic form. For the first form he recommends the use of a rhythmical movement of the thumb and index-finger during speech, and an instrument for beating time, of his own invention, called the muthonome. If the case is complicated by gutturo-tetanic spasm, he adds "lingual and guttural gymnastics, which consist in taking a deep breath before difficult words and phrases, and bringing the tongue into the pharynx, at the same time raising the point well toward the velum palati." His method is, after all, only a combination of preceding ones, but seems to have been effectual in producing, for a time at least, very good results.

The year 1841 is unique in the annals of this affection. In that year operation was proposed, hundreds of stutterers were operated on, but before the end of the year the surgeons themselves were convinced of the uselessness of operation. The idea was suggested to the mind of Dieffenbach, of Berlin, by the frequency with which stuttering and strabismus exist in the same patient, and occurred to him, he says, when a man asked, with a marked stutter, to be operated on for strabismus. The operation which he usually performed was section of the root of the tongue, sometimes with excision of a triangular piece throughout its entire length and breadth. This proceeding was based on the theory that stuttering is a purely local affection. The news of these operations soon spread to France, but at first without details, and there several others were invented, *e.g.*, cutting the hyo-glossi, genio-glossi, etc., varying with the different theories of the surgeons as to the cause of the trouble. At first cases were reported as cured by each of these methods. Later, relapses were said to have occurred. Then several deaths were reported, and operation was soon abandoned as useless by common consent. Dieffenbach himself admitted the extreme danger of the proceeding. The deaths were the result of secondary hæmorrhage and gangrene. The results attained immediately after operation seem to have been due to the impression on the nervous system of the patient, which wore off as soon as the effects of the operation subsided.

Since that time there has been a good deal written on the subject of stuttering, largely by stutterers them-

selves, both in and out of the profession; by Guillaume in France, Merkel, Klencke, and Kussmaul in Germany, Canon Kingsley and Bristowe in England, Hammond and Potter in America, and many others.

Guillaume lays especial stress on the disturbances of respiration. He points out the fact that the ordinary expiratory act is passive and simply elastic, while in speaking the inspiratory muscles are innervated during expiration, so as to allow only so much air to pass out as is necessary for phonation. The stutterer often expends his whole stock of air in one syllable. His lungs are then empty, and a deep inspiration is prevented by spasm of the glottis or irregular action of the diaphragm. Guillaume recommends a breathing exercise, consisting of a deep inspiration, held awhile, and followed by an expiration, slow and interrupted as in speech, but without sound. He also recommends fixation of the tongue high, a deep inspiration at the beginning of every clause, and the use of an interdental plate. The latter, he says, sometimes wonderfully changes a stuttering pronunciation.

Merkel lays especial stress on the fact that the difficulty lies in combining a consonant with the following vowel sound. He locates the trouble, not in the articulating, but in the vocalizing apparatus, or, farther back still, in the nerve-centres which govern that apparatus.

Gerdts thinks the trouble one of respiration. He says, however, that the spasm is induced by the patient using the mouth instead of the throat in talking. His idea seems to be to make vocalization more, and articulation less, prominent. At the same time he pays great attention to the breathing, which, he says, has been faulty, even when not speaking, in all of the 690 stutterers whom he has treated.

Bristowe likens stuttering to chorea.

Causation.—Among the many theories which have been propounded to account for the symptom under discussion, that which ascribes it to malformation or disease of the organs of articulation is one of the oldest, and one which held its ground longest. It is the foundation of all operative interference, and is readily disposed of. In many pronounced cases of stuttering the tongue and lips execute ordinary movements perfectly. No abnormality is noticed except during speech; and when organic trouble coexists, its removal does not entirely cure the affection. Any conceivable degree of deformity may exist and cause nothing but stammering, which is then proportional to the amount of the lesion.

Stuttering is not due to a faulty position of the tongue, as is shown by the constant relapses which occurred after treatment by Mrs. Leigh's method. It is true that in many cases the tongue is pressed against the floor of the mouth, and is affected with clonic spasm in this position. This is, however, not always the case, and when it exists it is a result, not the cause, of the malady.

The trouble is not a chorea of the muscles of articulation. The characteristic of choreic spasm is that it is irregular and jerky, and occurs during rest. The spasm of stuttering occurs only during a voluntary excitation of the speech-mechanism. Again, chorea, when it affects the lips and tongue, causes marked stammering, never stuttering. Chorea of the speech-centre, or coprolalia, causes a spasmodic ejaculation of words or phrases independently of volition, and the words are perfectly articulated.

That the trouble is due to confusion of ideas, or disproportion of words and ideas, is obviously false. Stuttering occurs in persons of every grade of mental power. The greatest disproportion between words and ideas occurs in acute mania, and leads, not to stuttering, but to a chaotic mixture of words and syllables. In most persons failure of ideas is marked by a drawl, not a stutter.

It is not due to a simple ataxia of the muscles used in speech. If it were, the patient could at once control the irregular movements by ceasing to speak. But when he does this, the spasm invariably persists for a short time. Again, stuttering is only occasional, and made worse when the patient's attention is directed to his speech; ataxia is constant, and is diminished by attention.

The theory that it is an inability to combine the consonant and vowel sounds is inadequate to explain the symptoms. The occasion of so combining them is often a proximate cause of an attack, somewhat as general convulsions are caused by teething or other peripheral irritation. But stuttering may occur on an attempt to utter a pure vowel sound entirely apart from a consonant.

In order to understand the phenomena presented, it will be necessary to review briefly the structure and physiology of that part of the motor speech-centres which serves for the production of articulate sounds. The processes which occur in the nerve-centres during speech are most of them unconscious, there being present to the mind only the primary volition, which is comparatively simple. The act of speech is based on stored-up motor memories of former acts of the same kind, which originated in childhood in reflex and accidental movements, perceived by the child, and afterward voluntarily executed. The details of these movements are carried out by a co-ordinating mechanism which has acquired its functions gradually, as a result of training. The motor impulse travels from the motor speech-centre in the left third frontal convolution, downward through the knee of the internal capsule, and reaches the medulla. The nerves carrying it here communicate with the articulo-respiratory centre, consisting of the nuclei of origin of the facial, pneumo-gastric, spinal accessory, and hypo-glossal nerves. These nuclei lie close together, and constitute practically one collection of cells bound together by fibres running in every direction. Here, and possibly also in the cerebellum, is effected the exact degree of innervation of all the muscles of articulation, so as together to produce the vowel and consonant sounds, and at the same time to approximate the vocal cords, and so regulate the respiration as to cause exactly the necessary amount of air to pass through the glottis. This exceedingly complex action is entirely apart from the conscious act of speech, and is only known to the sensorium through the intervention of the sensory nerves supplying the mucous membranes and deeper parts of the lips, tongue, and palate. It is one of the highest reflex actions, and, like most reflexes, is more or less under control from the cerebrum. The amount of innervation of each muscle is determined by lines of least resistance in the connecting fibres, which are formed as a result of repeated transmission of motor impulses, and are determined to a considerable extent by predisposition.[1] This whole system is probably under the influence of one or more controlling centres, which serve to check over-action, or the undue diffusion of nerve-force.

Stuttering is a disturbance of this co-ordinating mechanism. It may be due to abnormal excitability of the primary system, or to weakness of the inhibiting centre, probably the latter. The result is an over-action of the muscles innervated, and transmission of the impulse to other muscles more or less distant, sometimes even to those of the arms and trunk; the attempts of the patient to overcome the spasm only serve to intensify it, until the controlling centre resumes its function, or the patient ceases the effort to speak.

Several facts tend to show that the trouble is adynamic in origin—*e.g.*, the fact that patients usually stutter worst when tired; that persons sometimes stutter when exhausted, or during sickness, who do not otherwise; that stutterers are often, though not always, of weak or scrofulous constitution. The inhibiting influence of strong peripheral impressions, as seen in the results of operation on the tongue, is somewhat like the stoppage of epileptic convulsions by ligature or an encircling blister of a limb.[2]

This disturbance of equilibrium between the centres is often the result of an inherited tendency. It may follow severe illness, fright, or any shock to the nervous system. In such cases the trouble may pass off when the depressing influence ceases, or may persist for a long time, or through life. In any case the intensity of the disturbance depends much on the treatment and surroundings of the patient, anything like ridicule or punishment aggravating it tenfold.

OCCURRENCE.—Stuttering occurs in all ranks of society, and in most nations. The Chinese are said to be exempt, on account of the peculiar intonation of their language. It affects men much oftener than women, although trustworthy statistics on this point are lacking. Some authorities have thought that no women stutter; others place the proportion of women affected as high as thirty-five per cent. Kussmaul believes the fact to be due to the greater tact and delicacy of women, which fits them more readily in every way for their place in society.

SYMPTOMS.—These vary much in point of severity and mode of sequence of the spasm. In lighter cases, which are fairly under control, when one of the explosive consonants is met with, the organs of articulation remain fixed in their closed position for a moment, there is slight choking, and tremor of the facial muscles, an effort of the will is made, and the parts resume their function.

In rather more severe cases there may be added a good deal of thickening and tremulous movement of the tongue, and tonic spasm of the glottis. The breathing is then apt to be irregular, and the approximation of the vocal cords causes a crowing sound on inspiration, which is sometimes utilized for speech.

When the spasm occurs before speech has actually commenced, the trouble begins with tonic spasm of the glottis, there is tonic and clonic spasm of the tongue, lips, and face, and the diaphragm acts irregularly in its efforts to overcome the resistance at the rima glottidis.

In severe cases the attack may be brought on by any sounds, less frequently the open vowel sounds; the closure may be effected by the lips, tongue, or palate; the under jaw is set; there is marked tremor of the facial muscles, and sometimes even of the arms; the glottis may be closed so as almost or entirely to prevent respiration, or it may be opened at the same time that there is spasm of the respiratory muscles. In the latter case the lungs are emptied of air, and the patient must pause for a deep breath before he can proceed with his sentence. At the same time the face becomes flushed, the flow of saliva is increased, and the mental torture of the patient tends to prolong rather than cut short the attack.

DIAGNOSIS.—The diagnosis is usually easy. In addition to the clinical features given above, the duration of the malady should be carefully ascertained.

Stuttering almost invariably dates from childhood. Attention should be paid to the physical signs of organic brain disease.

The speech-defect which occurs in paretic dementia may simulate stuttering quite closely. There is here faulty enunciation of the separate consonant and vowel sounds, with marked tremor of the tongue and facial muscles. But there is not much disturbance of respiration; the tremor of the tongue and lips occurs when the patient is not speaking; above all, there are elision of syllables, and other evidences of partial aphasia. The history shows a recent development of the trouble.

On the other hand, stutterers with congenital mental defect and unequal pupils have been mistaken for paretics. Absence of other symptoms, stationary nature of the disease, and attention to the differences given above will then decide.

In clergymen and other public speakers there sometimes occurs a difficulty in speaking, which may be mistaken for stuttering. It is one of the occupation neuroses, of which the type is writers' cramp, and is due to exhaustion of the co-ordinating mechanism of respiration. Respiration, as pointed out above, is ordinarily reflex, but becomes voluntary when used for speech. Some speakers entirely empty their lungs before taking breath; the action of the reflex mechanism is then kept too long in abeyance. When this is habitual, the centres become exhausted and fail to respond to the reflex stimulus. The trouble usually begins in the glottis, which fails to open on inspiration; a crowing sound is produced when the speaker takes breath; the diaphragm and intercostals act weakly and irregularly, and the lungs cannot be promptly filled for the next sentence. This may happen only toward the end of the discourse, when the speaker is tired, but may become so marked that any attempt to speak causes great distress, and rest is then an imperative necessity. This affection differs from stuttering by occurring comparatively late in life, not involving the muscles of articulation, being rather of a paralytic than of a spastic nature. It ordinarily yields to rest and respiratory gymnastics.

Another rare affection, aphthongia, is probably allied to the preceding. Here the spasm occurs in the muscles supplied by the hypo-glossal nerve, and is brought on by any attempt to speak, so that articulation is rendered impossible. In the few cases recorded the disease has been caused by emotion or fright. During the attack the jaws and tongue are fixed; the sterno-thyroid, sterno-hyoid, and thyro-hyoid muscles may be in a state of clonic spasm, which begins and ceases with the attempt to speak. The prognosis seems to be good. Too little is known of the disease to speak of its probable relation to stuttering. It may be distinguished by the character and history of the attacks.

The speech-defects in multiple sclerosis, bulbar paralysis, etc., have been noticed in a previous article. (See Stammering.)

PROGNOSIS.—There is no doubt that sufferers from this affection may be aided by treatment, especially if the latter is vigorous and instituted early. The prognosis is better in non-hereditary cases, and in patients of strong will-power. Almost all writers on the subject have a favorite method of treatment, especially those who are connected with an institute for voice-training, and claim a large percentage of cures. Investigation shows that in most cases relapse takes place, after an even brilliant result. This should not discourage patients from effort, but it is necessary to bear in mind that only constant and long-continued exertion will overcome a vicious tendency fixed by habit. The difficulty tends to decrease with time, and many stutterers are able to master it at forty or fifty years of age. They are apt to ascribe this to some particular form of treatment, which they then ardently recommend.

TREATMENT.—Too much stress cannot be laid on beginning treatment early. The child should be kept, as much as possible, from association with stutterers. It should be remembered that he is sensitive as well to sympathy as to blame for his malady, and as little notice should be taken of it as possible, except in connection with stated lessons. He should be taught, when he has an attack, to stop speaking at once until he has mastered it.

Breathing exercises are very important. They may be given, following Guillaume, by causing the patient to take a long breath, hold it for a moment, and then let it out slowly, with occasional stops, but without sound. He should especially be made to take a deep breath at frequent intervals, and never speak with nearly empty lungs.

After breathing exercises have been continued for some time, the patient may proceed to the vowel sounds, first the most open one, *ä*, then *ā*, *ă*, *ĕ*, *ē*, *ō*, *ŏ*, and so on; then the aspirates, *hä*, *hā*, etc.; next the easier consonants in combination, *lä*, *lā*, *lē*, *lō*, *lū*, *mä*, *mā*, etc. Sentences may then be used in which the difficult sounds do not occur. Lastly, the explosives, *dä*, *dā*, *bä*, *lā*, etc., may be tried. With all of these the patient should be taught to lay the stress on the vowel sounds, so as to avoid the slight over-action with the consonants, which is usually the beginning of the spasm. One must be sure that the pupil has mastered each of the above classes before he is permitted to go on to the next.

We have a mass of evidence from stutterers, in the profession and out of it, testifying to the efficacy of rhythmical movements accompanying speech. They serve a twofold purpose—they divert the patient's attention, and give his sentences something of a sing-song character. They are aids, but are in no sense curative. The thumb and finger may be opened and closed, or any other movement made which is convenient to the patient. Somewhat the same effect is produced by elevating the tip of the tongue, as recommended by Mrs. Leigh, but it will

be better, in most cases, to draw the patient's attention to a more distant part of his body.

Therapeutic measures are of little value. Stimulants should be used moderately, if at all. Scrofulous and anæmic tendencies should be corrected, and the patients should be kept in good general health by exercise, cold sponging, and like measures.

The question is often asked, whether it is possible for an adult to master his defect without assistance from a teacher. That is entirely an individual matter. Some men have perseverance enough to educate themselves in this as in other respects. Proper teaching, however, saves much time and disappointment.

STYPTICS are medicines used locally to arrest hæmorrhage. They have the property of forming, with the albumen of the escaping blood, a solid, more or less adhesive mass, or coagulum, which mechanically closes the bleeding vessels. Of the numerous substances which coagulate albumen only the following are commonly employed: Tannin, alum, chloride of iron, subsulphate of iron, iodine, and nitrate of silver.

Their utility is very conspicuous in hæmorrhages from small blood-vessels, especially capillaries; but when a rapid flow of blood takes place from large arteries, they are quite powerless and should not be employed, unless other efficient hæmostatics cannot be applied.

Acidum Tannicum.—The coagulum which tannin forms with albumen adheres quite firmly, and usually quickly occludes small vessels. It is generally held that tannin also contracts the vessels; but in a series of very careful experiments it was found by Rosenstirn that even very concentrated solutions markedly dilate arteries, veins, and capillaries.

Tannin used as a styptic does not produce any notable irritation of the tissues, and causes neither pain nor subsequent inflammation. It is, therefore, preferable to other more irritating substances. It is most effective when applied in the form of fine powder immediately to the bleeding surface, all coagula having previously been removed by means of cold water.

It is often successful, even when it cannot be brought in contact, in large quantities, with the bleeding surface. Thus epistaxis commonly ceases after it has been snuffed up the nostrils. Concentrated solutions also sometimes arrest epistaxis.

To arrest bleeding after tooth extraction, finely powdered tannin should be freely applied to the bleeding surface by means of a piece of soft, moist sponge, or a pledget of cotton. Then a thick narrow compress should be applied over the sponge or cotton, and the jaws firmly closed by means of a roller passed around the head.

Tannin is used in metrorrhagia when the blood issues from small vessels of the cervix uteri. Several drachms are usually applied by means of a mass of cotton previously soaked in water and squeezed nearly dry, or by a soft, moist sponge. Sometimes suppositories of tannin, made with a small quantity of glycerine, or with oil of theobroma, are introduced into the cervix. Becquerel used suppositories consisting of tannin, four parts; tragacanth, one part; and bread crumb, a sufficient quantity. He applied them through a speculum, and kept them in place, until dissolved, by a mass of cotton saturated with a concentrated solution of tannin.

Tannin has also been employed in gastric, intestinal, and pulmonary hæmorrhage. Its utility in gastric hæmorrhage is very doubtful, as it probably cannot come into close contact with the bleeding surface. It should be tried only in cases in which the blood issues from small vessels, and administered in the form of powder or concentrated solution. In intestinal hæmorrhage, especially when the bleeding surface is in the lower part of the small intestine, as in typhoid fever, it is useless. If given, the pilular form of administration should be preferred. In hæmoptysis inhalations of atomized solutions of tannin, containing from one to ten per cent., are said to have been successful, especially in cases in which the bleeding was moderate but recurred frequently.

Alumen.—Alum may be employed in hæmorrhage from small vessels of any accessible part.

In epistaxis powdered alum, either pure or mixed with an equal quantity of gum arabic, may be blown into the nose by means of an insufflator or a paper funnel, or a saturated solution may be thrown into the nostrils. In obstinate bleeding from leech-bites a dossil of cotton wool may be impregnated with a saturated hot solution of alum and pressed upon the bleeding point. The same procedure may be adopted in severe hæmorrhage after tooth extraction, or alum in powder may be applied by means of soft, moist sponge, or a pledget of cotton wool, which should be firmly fixed upon the bleeding surface.

Alum is frequently used in hæmorrhage from the cervix uteri. Several ounces of a saturated solution may be injected into the vagina, the patient being in such a position as to keep the solution in contact with the cervix. Pledgets of cotton wool, soaked in a saturated solution of alum, may be applied to the bleeding surface.

In hæmoptysis solutions of alum, containing from one to five per cent., are employed in the form of spray. The inhalations are held to be most useful when the hæmorrhage is moderate, but recurs frequently at short intervals.

Liquor Ferri Chloridi.—The solution of chloride of iron is the most powerful styptic. It coagulates not only the blood which has escaped from vessels, but also that within the vessels with which it comes in contact. Even diluted with two or three parts of water, it condenses the tissues, contracts the blood vessels, especially arterioles and venules, and produces more or less irritation, often followed by inflammation.

Its action on the albumen of the blood is not instantaneous, from twenty to forty seconds elapsing before a firm coagulum results. If present in considerable excess, it gradually dissolves the coagulum.

Solution of chloride of iron is applicable in cases of hæmorrhage in which less irritating styptics, such as tannin and alum, are inefficient, and it may be employed in all accessible hæmorrhages from small vessels. In recent wounds, when other hæmostatics have failed to arrest the bleeding, the solution, undiluted or diluted with two or three parts of water, is frequently used. Before its application the bleeding surface should be thoroughly cleansed from blood and coagula, so that the styptic may come into immediate contact with the open vessels. A clean sponge, previously steeped in ice-water and squeezed out, should then be firmly pressed upon the bleeding surface, until a mass of cotton saturated with the iron solution, and well pressed between the fingers to remove the excess of the chloride, is ready for application. The cotton should be applied instantly after the removal of the sponge. Then another mass of cotton wool, moist but not wet with the iron, should be applied over the first and gently pressed upon it. If the bleeding ceases, dry cotton may be placed over the moist masses, and firmly fixed to the part by appropriate dressings. If, however, the flow of blood should still continue, the compresses should be removed and others applied in the same manner. It is important that the cotton compresses be only moist, not dripping wet, with the solution of chloride of iron, as an excess of the latter exerts a solvent action on the coagulum. As a rule, the compresses should not be removed before the third day. Then cold water should be gently injected into the masses of cotton, so that no force may be required for their removal.

In hæmorrhages from cavities, such as the nose, vagina, uterus, and rectum, the solution of chloride of iron, diluted with three or four parts of water, is usually ef-

fectual. Such a solution was used by Barnes and others to arrest post-partum hæmorrhage, being slowly and carefully injected into the cavity of the uterus. Breisky and some other German writers maintain that a very dilute solution, containing only sufficient chloride of iron to impart to the water a deep wine-yellow color, is equally effectual. In uterine hæmorrhage occurring at a late period after labor, a mixture of equal parts of water and solution of chloride of iron is sometimes applied to the cavity of the uterus by means of a pencil or a sponge.

A weak solution of chloride of iron has been given internally to arrest gastric and intestinal hæmorrhage. Some good may possibly follow in gastric hæmorrhage, if the bleeding occurs slowly from small vessels; but in intestinal hæmorrhage no reliance should be placed on styptics.

Good observers affirm that they have found inhalations of the spray of dilute solutions of chloride of iron, containing from one to five per cent., very efficient in severe hæmoptysis, after subcutaneous injections of ergotin had failed.

Liquor Ferri Subsulphatis.—This solution, commonly called Monsel's solution, is supposed to coagulate blood as speedily and firmly as the chloride of iron, and to be less irritating to the tissues. Whether it contracts blood-vessels has not been determined experimentally, but it probably is less active in this respect than the chloride.

In hæmorrhages from accessible parts it may be applied undiluted, or diluted with two or three parts of water, in the same manner as the solution of the chloride. It is generally preferred to the latter in bleeding from cavities, such as the nose, mouth, throat, and rectum.

Cotton steeped in solution of subsulphate of iron and then dried, is known as hæmostatic cotton. It is applied to bleeding surfaces, previously well cleansed, in a thick layer, and firmly supported by a compress and roller.

Dry subsulphate of iron, obtained by evaporating the solution, made into suppositories with cacao butter, is frequently employed to arrest hæmorrhage from the rectum and the cervix uteri.

Iodine.—In the form of tincture, iodine is used as a styptic in some kinds of uterine hæmorrhage. Some authors state that the best results may be obtained from a stronger solution, known as Churchill's tincture, consisting of seventy-five grains of iodine, ninety grains of iodide of potassium, and one ounce of alcohol. This preparation has been highly recommended for the arrest of metrorrhagia due to uterine fibroids and cancer of the cervix. It may be injected into the uterine cavity if necessary, after previous dilatation of the cervix, by means of a hard rubber syringe, the nozzle being pushed near to the neighborhood of the fundus. The injection should be made very slowly, and a mass of cotton should be placed at the os uteri to prevent the iodine, as it escapes from the cervix, from passing over the vaginal wall. The quantity which should be injected varies, but should never exceed one drachm. Sometimes the tincture is applied to the uterine cavity by means of a pledget of cotton wrapped around an applicator. Much weaker solutions of iodine have been successfully employed for the arrest of metrorrhagia.

Argenti Nitras.—Nitrate of silver coagulates albumen and strongly contracts blood-vessels. It is never used in ordinary hæmorrhages, but is very convenient for the arrest of obstinate bleeding from leech-bites, a pointed stick being gently pressed upon the bleeding point. *Samuel Nickles.*

SUDAMEN. An inflammatory affection of the skin, involving the closure of the sweat-ducts, with the formation of numbers of discrete, minute, clear vesicles, from the size of a pin-point to that of a pin-head, rising directly from the skin, with little or no congestive areola. The vesicles usually contain a clear acid fluid which is not sticky, and dries up without leaving any crust. The eruption usually occurs in the course of fevers or other severe general diseases. It was formerly supposed to be a substantive disease, and under the terms *suette miliaire*, *suette de Picardie*, etc., was even described as epidemic.

By many physicians the affection is supposed to be a form of that previously described in this work under the name of Miliaria. The distinction usually made is that, while in miliaria there is always a congestive base, in sudamen the vesicle rises from the unchanged surface of the skin. To this it may be added that miliaria is almost always connected with excessive sweating, in persons otherwise healthy, while sudamen is a concomitant of febrile or other exhausting disease. The treatment is the same as that of miliaria. *Arthur Van Harlingen.*

SUET (*Sevum*, U. S. Ph.; *Sevum Præparatum*, Br. Ph.; *Sebum Ovile*, Ph. G.; *Suif de Mouton*, Codex Med.; Mutton Suet, Mutton Tallow. The Codex also recognizes the similar product of the Ox, *Suif de Bœuf*, *Suif de Veau*, as well as the marrow, *Moelle de Bœuf*). The part of the animal taken for this preparation is the same that yields the hardest and best lard, or beef tallow, namely, the thick mass of fat lying along the loins and surrounding the kidneys. The whole tissue is suet, the fat melted out and purified is tallow.

The preparation is exceedingly simple, although not always well done. It consists in first cleaning the suet from connective tissue, vessels, blood, etc., then cutting it in small pieces and washing in cold water, or allowing it to soak for a few hours in water; then it is boiled with a little water until the tissue is broken up, strained, and poured away to cool; the last portion of water is then removed by prolonged, moderate heat, which should not be allowed to rise above the boiling point of water. In the laboratory the steam kettles offer the most perfect means of "trying out" lard and tallow.

Mutton suet has no medicinal properties not common also to the other animal fats, excepting greater hardness, a higher melting point, and perhaps superior keeping qualities to most of them. It consists of the usual glycerine fats, *stearin*, *palmitin*, *olein*, etc., with the former in excess, and the latter at a minimum. The pharmacopœial description is as follows: "A white, smooth, solid fat, nearly inodorous, gradually becoming rancid on exposure to air, having a bland taste, and a neutral reaction. Soluble in 44 parts of boiling alcohol, in about 60 parts of ether, and slowly soluble in 2 parts of benzin. From its solution in the latter, kept in a stoppered flask, it slowly separates in a crystalline form on standing. It melts between 45° and 50° C. (113° and 122° F.), and congeals between 37° and 40° C. (98° and 104° F.)." Suet forms about one-fourth of Mercurial Ointment and one-half of Tar Ointment. It is also an extensively used domestic cerate.

Allied Substances.—Numerous fats of domestic and wild animals are in common household estimation for one purpose or another, with very little real difference from each other except in odor and hardness. Goose, chicken, and skunk oils are extensively used in country families all over New England. Something more distinctive, and having peculiar claims to attention, are the preparations of grease obtained from the wool of sheep, and called by the commercial names of "Lanolin" and "Agnine, etc." The former of these was introduced as a patented article by Liebreich some five years ago. His process for preparing it is said to be as follows: "He takes the suds from the washings of wool in the mill, submits it to the action of a centrifugal machine which separates the soapy, oily suds from the dirt associated therewith, decomposes the suds by an acid, whereby the acid and the saponifying alkali unite, and the saponified wool-fat is separated, combined with about one hundred per cent. of water; this is thoroughly washed with cold water, then heated so as to separate the water and wool-fat, and again combined with a definite proportion of water, and lanolin is the result." Or the wool itself may be treated with alkaline water and the suds produced proceeded with as above; or the fat finally may be dissolved out with petroleum, benzin and obtained by evaporation, and mixed with a suitable proportion of water (*Therapeutic Gazette*).

Lanolin is a soft-solid, adhesive, ointment-like, fatty substance, of a light yellow color, a woolly odor, and slight oily taste; rubbed upon the skin it at first greases it, but soon it disappears by absorption, leaving the skin soft, smooth, and nearly clean; it mixes with its weight of water smoothly. It should be neutral in reaction, free from glycerine and ammonia, and should never become rancid. It contains a large amount of cholesterin. It is not in the least irritating. The miscibility with water, and ready absorption by the skin, make this substance of especial value in making a class of ointments which of late had fallen considerably, and deservedly, into disuse from their unreliability, viz., those containing active medicines used with the hope of their absorption; mixed with lanolin these substances are unquestionably absorbed, and iodide of potassium, mercury, aconite, atropine, morphine may be given in this way through the skin; as a simple protective also it equals the other fats. It is so sticky that, for convenience in using, it is better mixed with a third or half of some other fat (lard or tallow).

Agnine is the name given to another preparation from the same source, apparently unmixed with water; it is harder, darker, and less agreeable in color and odor than lanolin, to whose uses it is said to be adapted.

W. P. Bolles.

SUGAR (*Saccharum*, U. S. Ph.; *Saccharum Purificatum*, Br. Ph.; *Sucre de Canne*, Codex Med.); Cane Sugar, Saccharose, Sucrose, etc., $C_{12}H_{22}O_{11}$.

Common sugar is one of a group of soluble, sweet-tasting compounds formed by plants in the process of assimilation, or provided in their seeds, fruits, or other organs in storage for later consumption. This particular variety, although pretty widely diffused among plants, is in practice obtained from five or six only, where it is very abundant. These are:

Saccharum officinarum Linn.; Order, *Gramineæ*, the Sugar Cane, a large East Indian grass, whose solid stems are laden with it, furnishes most of the sugar of the world.

Beta vulgaris Linn.; Order, *Chenopodiaceæ*, the Sugar Beet, a South European plant, long cultivated for fodder, but utilized for sugar during the present century. It supplies half the sugar of the continent of Europe.

Acer saccharinum, Order, *Sapindaceæ*, the Sugar of Red Maple, yields the Maple Sugar of America.

Saguerus Rumphii Roxb. (*S. saccharifer* Bl.); Order, *Palmæ* and other Palms, supplies sugar, drink, and liquor in India.

Sorghum saccharatum Pers., another grass, is cultivated for sugar in China, and very slightly in the United States.

Sugar has been known from a very remote period in India, where the cane has been used as food from prehistoric times. It found its way into Europe about the beginning of the Christian era, probably as a natural exudation, like manna, from the wounded canes. Its preparation by extracting and boiling the juice, and its partial refinement, are developments of the first third of this era. At first sugar in Europe was expensive, a rarity, and only used as a medicine or luxury; its general use as a food here dates back only two or three hundred years. Even the last half century has witnessed an enormous extension of it.

PREPARATION.—The canes are cut when well grown, stripped of leaves, and crushed between strong iron cylinders which press out their sweet juice. This is immediately neutralized with a little milk of lime, to prevent decomposition of the sugar and souring, as well as to precipitate some of its impurities. It is then heated, the albuminous "scum" removed, and the clear juice boiled down until it will crystallize upon cooling, when crude sugar and its mother liquor (molasses) are the results. To this outline many details must be added to give an idea of modern sugar-making. The mill has been developed to give equable pressure whatever the thickness of the feed, and series of vacuum pans have, in most places, superseded the old open boilers; while some processes of purification or filtration have been put in use during the boiling at the mills. The raw or brown sugar produced in this way is then usually exported to northern countries—Europe and America—for refinement. This consists, with many variations and details, in redissolving the sugar, straining it, and precipitating impurities again, perhaps with lime; by boiling with blood-albumen and by filtration through long columns of animal charcoal; the clarified syrup is then condensed in vacuum boilers until it will crystallize on cooling; the sugar so formed is drained in moulds, or dried in centrifugal machines, and finally sold in loaves, lumps, fine crystals (granulated), or powder. The drainings from the sugar in this last crystallization, constitute the Sugar-house Syrups of the market.

The process of extracting sugar from the Beet consists in cleaning, grinding, and pressing the roots to obtain the juice, or, to get a cleaner product, in slicing them and subjecting them to a sort of repercolation process; this liquid is then heated with lime and injected with carbonic acid, which precipitate albuminoid and other impurities, and finally the lime itself is freed from its combination with the sugar. The clarified juice is then further filtered through animal charcoal, and finally evaporated as above.

From the Maple the sap is collected in the early spring by tapping the trees and attaching suitable receptacles; the sap is then simply boiled down in iron pots until it will become solid upon cooling, and is then run into pans.

There are several grades of imperfectly purified sugar sold for family use, as brown-, yellow-, coffee-sugar, etc., but none of them is suitable for medicinal or pharmaceutical uses; neither is the maple sugar.

Sugar scarcely needs a description. That of the market is practically pure—a little earthy residue, occasionally a little coloring matter, and perhaps a trace of one of its derivative sugars may be found, but often nothing; the most tempting adulteration is glucose, but this in crystallized or granulated sugars is rare. The Pharmacopœia gives the following tests of its purity: "Neither an aqueous nor an alcoholic solution of sugar, kept in large, well-closed, and completely filled bottles, should deposit a sediment on prolonged standing (abs. of insoluble salts, foreign matters, ultramarine, Prussian blue, etc.). If a portion of about one gram of sugar be dissolved in ten cubic centimetres of boiling water, then mixed with four or five drops of test solution of nitrate of silver,* and about two cubic centimetres of water of ammonia, and quickly heated until the liquid begins to boil, not more than a slight coloration, but no black precipitate, should appear in the liquid after standing at rest for five minutes (abs. of grape sugar and of more than a slight amount of invert sugar)." Sugar is soluble in half its weight of cold, in one-fifth of its weight of boiling, water, in one hundred and seventy-five parts of alcohol; not soluble in ether. It deviates polarized light to the right. It forms compounds with both alkalies and acids. It keeps perfectly in the air, and pretty well in concentrated solutions (syrups). In dilute solutions it is readily decomposed by several fungi, the commonest of which is the yeast plant, *Saccharomyces Cerevisiæ*, under whose influence alcohol and carbonic acid are produced. Acetic, lactic, and butyric acids are also formed from it by their specific ferments. By heat, diluted acids, and in other ways, cane sugar is separated into dextrose (grape sugar) and levulosan, or uncrystallizable sugar. Caramel is an empyreumatic product made by heating sugar until it becomes brown. It is used in coloring foods and liquors.

ACTION AND USE.—Sugar is at present a very important food, whose consumption is constantly increasing as its cost is becoming less, and is also a valuable preservative of other foods, as fruit; but it has no medicinal importance whatever, excepting the negative one of increasing acidity of the stomach in certain dyspeptic conditions, and of increasing the glycosuria and discomfort of diabetics. In pharmacy it has several applications, first as a preserver of some unstable chemicals, as iodide, suboxide, etc., of

* Five per cent. solution in water.

tron, and of fruit juices; secondly, as an agreeable vehicle, as in the syrups and troches; and, thirdly, as a pill covering.

PREPARATIONS.—Syrup, or simple syrup, as it was formerly called (*Syrupus*, U. S. Ph.), is a solution containing sixty-five per cent. of sugar in distilled water. The medicinal syrups are made either from this as a basis, or directly from sugar, or frequently from both. One of them, Syrup of Lime (*Syrupus Calcis*, U. S. Ph.), is a five per cent. solution of lime in combination with some of the sugar, which in this syrup is only thirty per cent. of the whole. All the Troches (*Trochisci*), contain sugar as their principal basis, excepting the Troches of Cubeb, which contain but a trifling amount. Both the officinal confections are made with it. Besides these classes of preparations, it is present as a flavor in many others, as Elixir of Orange, Sweet Tincture of Rhubarb, etc.

ALLIED SUBSTANCES.—If the derivatives of sugar and its natural varieties were to be included here, the list would be very long. The cane itself, when immature, contains a good deal of uncrystallizable sugar; molasses consists mostly of it, which is not exactly like the typical sugar. It is also easily decomposed, as seen above, into two sugars, neither of which is exactly like itself. Many fruits are sweet by reason of their glucose or grape sugar, others because of the presence of an uncrystallizable compound generally called fructose. Some of the glucosides in their decomposition yield sugars of peculiar properties. The sugar developed in malt is different from that of the cane, and called maltose. The following have some commercial importance and relation to cane sugar: *Lactose*, see Milk, Sugar of; *Glucose* (starch sugar, etc.), an artificial sugar prepared on a very large scale, and used in the arts and especially in cheap confectionery; it occurs as a syrup, commercially called "glucose," and as a yellowish-white crystalline cake or powder, "Starch Sugar." It is very much less sweet than sugar, and has, besides, a mawkish taste *Manna*, *Liquorice*, *Honey*, and *Glycerine* resemble sugar in taste and in some of their applications.

Saccharin.—This interesting substance was first produced from toluene, a coal-tar compound, in 1879, by Dr. C. Fohlberg, of New York. Its chemical name is given as anhydro-ortho-sulphamin-benzoic acid. It is a white, crystalline powder, soluble in something more than two hundred parts of cold water, more freely in hot water, and abundantly in alcohol and ether. It has no chemical relation to the sugars whatever, and was named saccharin, a word already applied to one of the sugars, solely on account of its intensely sweet taste, which is said to be two hundred and eighty times that of sugar; one part in seventy thousand of water is distinctly tasted. Saccharin appears to be a stable compound of no action whatever upon the body, five grams a day producing no symptoms, the use of which by diabetics and dyspeptics may satisfy that craving for sweet which makes their diet so unsatisfactory; half a grain is enough to sweeten a cup of coffee, half a dozen grains for a whole day's food. It is eliminated by the urine unchanged.

W. P. Bolles.

SUICIDE. The term suicide, to express the act of self-destruction, was probably first employed by Desfontaines in the last century. It is derived from the Latin words *sui* (self), and *cædere* (to kill). Synonyms: Fr., *Suicide;* Ger., *Selbstmord;* It., *Suicidio;* Legal, *Felo de se.* Other rarely employed terms are: Gr., αὐτοχειρία; and Lat., *Propriicidium.*

Suicide is a voluntary human act of self-destruction, which, when undertaken with "malice aforethought," is a crime under the law; and only under these circumstances should it be called self-murder, and be punishable.

It is claimed by some writers that the act is always due to some disorder of the mind at the moment of its accomplishment.

HISTORY.—From the earliest times of which we have record the custom of self-destruction has existed to a greater or less degree, and it would appear that the peoples of antiquity were so taught by their religion that they could look upon the act as logical, and perform it with stoicism.

The religion of Brahma justifies suicide, and looks upon it, under certain conditions, as an honorable and praiseworthy act, which is often solemnized in a public manner. Fanatics in India, who believe in the transmigration of souls, seek an improvement in their condition and a freedom from present ills by courting death. The Brahmins have in a great measure given up their terrible custom of prostrating themselves before the car of their gigantic idol Juggernaut, to be crushed to death. Still they occasionally do it, and the women throw themselves upon the funeral pyres of their husbands.

Although held in honor among the people of the Orient, it was always rare in Persia, and is an exceptional occurrence among the Turks. The teachings of the Koran are opposed to it. Mahomet forbade it, and inculcated a spirit of patience in adversity. Here, too, the belief in fatalism probably exercised a marked influence, and the people were not given to philosophic thought, as were those of Greece, where many great men have sought death at their own hands.

When circumstances warranted the act, it was considered, in ancient Greece, a virtue for men to destroy themselves, thus escaping human ills, and, as they supposed, ameliorating their condition.

According to Legoyt,[1] Strabo relates as an historical fact that the inhabitants of the Isle of Ceos, in the Grecian Archipelago, poisoned themselves after reaching the age of sixty, so that the younger could have greater abundance; and Montaigne says that the senate of Marseilles, which then belonged to Greece, placed poison at the disposition of those who wished to commit suicide, when their motives were approved of.

The Hebrews, it would appear, scarcely knew suicide, and few cases are recorded. The Bible gives accounts of the self-destruction of Samson, Eleazar, Saul, Judas, and others.

The Celts were taught the immortality of the soul and their divine origin, still, suicide for the old and infirm was encouraged.

At Rome we find many noted suicides recorded, including that of Junius Brutus, and under the reign of Tiberius they appear to have increased in frequency. From the fifth to the twelfth centuries suicide almost wholly disappeared, but in the next century revolutionary ideas prevailed, and the previous influence of the Christian religion was so far lost that all classes of society suffered from a revival of suicide. Jews now resorted to it freely as a means of escape from hardships, and to avoid disloyalty to their faith.

A decided increase is noted from the beginning of the sixteenth century, due to a disregard for religion and a revival of customs of antiquity.

In China and Japan men of honor have long resorted to self-inflicted death.

In Africa it was not rare for individuals and whole bodies of men to commit suicide, and Carthaginian generals often destroyed themselves after defeat.

The increase of suicide in civilized countries during the present century is shown by carefully gathered statistics, and conceded by most writers.

STATISTICS of suicide began to be systematically collected and studied only in the present century, official statistics being published in several European countries during the first twenty years of the century.

The statistics here made use of are, for the most part, drawn from the excellent work of Morselli.[2]

In 1840, Farr, the director of English statistics, calculated that the average annual number of suicides in England and Wales was 62.8 per million inhabitants. I have calculated from Morselli's table, covering the years from 1830 to 1876, and made up from the work of various observers, and find the proportion to be 66.6 per million.

The number of suicides is probably much greater than is indicated by official reports, and this may vary in different countries.

The following table shows the proportion of deaths by suicide in various countries in 1882 :

Countries.	Estimated population.	Deaths by suicide.	Per 1,000,000 inhabitants.
Austria	22,316,567	3,530	158
Baden	1,596,206	283	177
Bavaria	5,389,732	724	134
Belgium	5,655,197	595	105
Denmark	2,008,100	513	255
France	37,769,000	7,213	191
Italy	28,596,512	1,389	49
Prussia	27,796,189	5,312	191
Saxony	3,040,000	1,128	**371**
Sweden	4,579,115	482	105
England and Wales	26,413,861	1,965	74
Ireland	5,097,853	105	21
Scotland	3,785,400	167	44

The German and Scandinavian races furnish the largest numbers. Only a few States in this country furnish accurate information, and there are no statistics for the whole of the United States.

The following table shows the number of deaths by suicide in Massachusetts, Rhode Island, and Connecticut in the years named.

Years.	Massachusetts.		Rhode Island.		Connecticut.	
	Total.	Per 1,000,000 inhabitants.	Total.	Per 1,000,000 inhabitants.	Total.	Per 1,000,000 inhabitants.
1870	91	62	27	124	....	....
1871	122	82	19	84	....	....
1872	117	76	18	77	....	....
1873	117	74	8	33	....	....
1874	115	71	18	72	....	....
1875	159	96	26	101	....	....
1876	119	72	18	60	49	[illegible]
1877	163	98	[illegible]	83	52	84

1880	133	75	10	36	48	77
1881	165	88	23	82	69	109
1882	162	88	31	109	65	101
1883	167	89	25	....	....	....
1884	184	96	85	....	....	....

The population is here calculated from the average annual increase since 1880.

In an editorial, which appeared in the *Medical Record* of August 14, 1880, it is stated that 60,000 persons kill themselves annually in Europe, and assuming that the same ratio exists here, nearly 10,000 suicides would occur in America.

Dr. John Lee,[3] of Philadelphia, has found that during the period from December 31, 1871, to January 1, 1881, there were fifty-three suicides in each thousand coroner's inquests held in the city of Philadelphia. Out of the 636 cases recorded, 444 were married persons, 24 were minors, and the greatest number occurred between the ages of thirty-five and fifty.

In statistical tables prepared by Dr. John T. Nagle,[4] of New York, covering a period of eleven years, ending December 31, 1880, it is shown that 1,193 males and 328 females committed suicide. Between the ages of ten and fifteen there were 15 ; between thirty-five and forty the greatest number was found, viz., 212 ; and between eighty-five and ninety there was only 1 ; 430 were single, 759 were married, and 137 were widowed. The means employed by the greatest number was poisoning, which gave 503. Those dying from firearm wounds numbered 397 ; 239 died by hanging ; 175 by cut and stab wounds ; 101 by drowning ; and 82 by leaps from heights. Of German birth there were 627 ; of Irish, 213 ; of English, 82 ; and 368 were native born, the remainder being distributed among natives of twenty-two different countries.

One table shows that the suicides for the year 1880 were :

New York City	152,	an average of	12.59	per	100,000	inhabitants.
Philadelphia	68	" "	8.03	"	"	"
Richmond	1	" "	1.54	"	"	"
Washington	18	" "	10.13	"	"	"
San Francisco	88	" "	37.65	"	"	"
Boston	40	" "	11.03	"	"	"

The same year we find in

Berlin	308,	an average of	27.44	per	100,000	inhabitants;
Vienna	230	" "	31.67	"	"	"
London	352	" "	9.34	"	"	"
Leipzig	84	" "	57.04	"	"	"

In the reports of the New York Board of Health for 1886, I find that 223 deaths from suicide are recorded ; 58 native born, and 165 of foreign birth, 98 of whom were Germans. Firearms were used 62 times ; the rope, 37 ; cutting instruments, 29 ; drowning caused 16 deaths ; Paris green, 11 ; "Rough on Rats," 8 ; and leaps from heights, 15. As regards sex, 172 were males and 51 females. The period between thirty and thirty-five years of age gave the greatest number (31 cases).

During the year ending September 30, 1887, I find 225 suicidal deaths ; 175 males and 50 females. The whole number, and the proportion of the sexes, conforming closely to the statistics for 1886. Paris green was employed in 11 cases, arsenic in 8, and rat poison ("Rough on Rats") in 12.

According to the London *Lancet*, the number of suicides in France during 1876 was 5,617. Of these 4,435 were men.

Morselli believes in a law of continual increase, and shows by a table that the increase per cent., from 1827 to 1852, was from 100 to 238.

It is shown by one of his tables that Saxony, which furnishes the largest number of suicides, has suffered an increase from 158 per million inhabitants in 1836–40, to 391 per million in 1877.

Another table prepared from the statistics of Italy, from 1864 to 1877, shows an increase from 29.2 to 40.6 per million.

From these and other data, the following law is formulated :

"In the aggregate of the civilized states of Europe and America, the frequency of suicide shows a growing and uniform increase, so that generally, voluntary death since the beginning of the century has increased, and goes on increasing more rapidly than the geometrical augmentation of the population and of the general mortality."

In the combined central and southwestern states and provinces belonging to Prussia the proportion of 150 suicides in the million is given. Morselli says :

"The synthetic and most certain law which springs out of these facts, is that in the centre of Europe, from the northeast of France to the eastern borders of Germany, a *suicidigenous* area exists, where suicide reaches the maximum of its intensity, and around which it takes a decreasing ratio to the limits of the northern and southern states."[5]

Nature.—The question of the nature of the act of self-destruction is a difficult, and a delicate one withal, to decide, but its great importance calls for much careful attention. Morselli says suicide is a social fact, and its nature "may now be reckoned among the most certain and valuable discoveries of experimental psychology ;" and further on, characterizes it as "an effect of the struggling for existence and of human selection, which works according to the laws of evolution among civilized people." But the question arises, is a given suicide, at the moment the act is committed, in the full and free possession of his faculties, and should he be held responsible for his movements ? If the act be always due to a morbid condition of mind (as claimed by Dr. Liebman, in a paper read before the Medical and Chirurgical Faculty of Maryland, April, 1881), it should not be punishable as a crime ; nor would, in this event, the punishment carry with it the intended restraining influence upon other would-be suicides. The mind which could conceive and plan so foul a deed would not, in all likelihood, be influenced by the thought of legal punishment in case of an unsuccessful attempt.

Insanity is probably present in the vast majority of suicidal attempts, and the number of those who act calmly and in the possession of their faculties must be much smaller than is generally supposed. Many obscure cases are difficult to explain on any other theory. There is a

want of motive. The surroundings and station in life of the suicide are the best, and so far as can be learned, the social, financial, domestic, and other relations are only such as would be conducive to life and happiness. Such cases are more common in so-called epidemics of suicide. If the attempt has not resulted in death, evidences of insanity often soon appear, and make it clear that mental irresponsibility existed at the time.

In other cases insanity may have been previously known or suspected from conditions present, either immediately preceding the act or at some more remote period, and still no decided symptoms may have shown themselves until after an attempt at suicide.

An hereditary mental defect may have been known to exist, the person regarded as eccentric, and the attempt not unlooked for.

Organic disease, excesses, venery, onanism, etc., may have been the cause of a mental aberration whose first outward sign has been the suicidal attempt.

Hammond says:[6] "Closely allied to emotional homicidal impulse is that form of mental derangement which consists in an *emotional impulse to the perpetration of suicide.* The conditions may coexist. In some cases the contemplation of the act is attended with feelings of pleasure. He is neither governed by delusions nor by logical reasons. He is actuated by a passion which it is pleasant for him to gratify. When the impulse has passed, he looks back upon it with horror, and shuddering at the escape he has made, perhaps seeks medical advice."

Automatic suicide, or suicide by impulse, is closely allied to that of the insane, and like it, occurs without apparent cause. The sight of a weapon, the finding of one's self upon a height or by the river's side, or favorably situated for the accomplishment of the act, being sufficient for the attempt. In non-success the circumstances of the act are more or less confused in the suicide's mind, and the only safety for those thus impelled is to hasten from the scene. Some persons appearing to be conscious of this outward influence, avoid suggestive situations, and feeling themselves powerless to resist, ask that precautions be taken to prevent the act.

Suicide by suggestion is well illustrated in a personal experience of Sir Charles Bell, when surgeon of the Middlesex Hospital, which is related by Wynter.[7]

While being shaved, he told his barber of an operation he had just performed on a man who had made an unsuccessful attempt to cut his throat, and explained the anatomical reasons for the failure. The barber, excusing himself, went into an adjoining room, and was found a few moments later with his throat cut in the proper anatomical situation to assure success.

Epidemic suicide, due to a neuropathic state of the system of those living under the same influences, is well known to neurologists, and many instances have been observed. An epidemic among the women of Miletus is recorded, at a time when the men were away at war, which reached great proportions and was checked by a decree, that the naked bodies of those who killed themselves should be exposed in public with a rope about the neck. In Mexico and Peru the inhabitants killed themselves in great numbers, it is said, after the invasion by Spain. Mansfeld had an epidemic in 1697, according to Sydenham. There was one at Versailles in 1793, and one occurred at Rouen in 1806, and at Stuttgart in 1811.

Some years ago five inmates of the Hôtel des Invalides, in Paris, hanged themselves upon the same crossbar within a fortnight.

Double and *multiple* suicides are occasionally recorded. The former usually consisting in the simultaneous death of man and wife, or two lovers or friends; the latter in the concordance of suicide of bodies of men, such as is said to have occurred in China among the philosophers of the Confucius School, when deprived of their books by the order of the emperor Chi-Koang-Ti.

Feigned Suicide.—Although the term is not a strictly proper one, it applies to those cases occasionally met with in which, to excite sympathy, secure desired ends, afflict friends, or for some other reason, a person makes it appear that he has made an attempt upon his own life.

Child suicide requires special notice, as it is not uncommon to find quite young children, even as young as five years, taking their lives for trifling cause, following impulse and sentiment without having the restraining influence of mature judgment, and the power of comparison and thought for anything beyond the present.

By nature children are sensitive to slights and injustice, easily depressed, fretful under restraint, and at times revengeful. They have vivid imaginations, are quick to imitate, but are defective in the power to reflect and form just conclusions. The sense of responsibility is wanting, so that no sooner is the act conceived than it is put into execution.

The belief of Durand-Fardel,[8] that the act of self-destruction is usually accomplished with much self-possession, and after reflexion, cannot apply to suicides in childhood (see, also, under Age).

Suicide following homicide is not very uncommon, but the subject is almost always melancholic. Esquirol tells of a Belgian woman who threw her four children into a well and jumped in after them. Both sexes include their children in the death they give themselves, but women would appear more inclined to this than men. In rare cases both parents conspire to kill their children and then themselves; such a case is related by Esquirol, and one has recently occurred in Paris.

Causes of Suicide.—In former times, and indeed at the present day in some countries, as we have seen, whole masses of people, as well as individuals, under the influence of their religious or philosophic beliefs, and following the customs of their forefathers for generations, have in great numbers become the subjects of self-destruction. No such custom is to be found to-day in any civilized country, but efforts to do away with it in India have failed, and we must put down fanaticism as one cause of many self-inflicted deaths. No encouragement is given to the act in enlightened lands, but, on the contrary, all laws, both human and divine, are strict in its forbiddence. Still, suicides have been shown by careful students of the subject to be on the increase, and we naturally inquire what are the causes which contribute to this state of affairs, and why do men take their own lives at all.

The causes are twofold: A subjective condition may exist which predisposes the individual to the act, or his environment may be such as to produce an objective state favorable to suicide. The pathological or other subjective condition may coexist with the surroundings which furnish the determining cause, or the one or the other may be wanting.

Predisposing causes to suicide are quite numerous, but heredity is one of the most important. The transmission of a suicidal tendency is an established fact of which many instances are known to alienists, and which forms a familiar phase of the practice of the family physician.

This transmitted tendency may lie dormant, or make its presence suspected by the development of mental disease; or the suicide may have been looked upon for years as one about whom there was "something strange," without any actual disease or decided symptoms of nerve or mental trouble being apparent.

The offspring of a suicidal parent appears to inherit a system favorable to the development of nervous affections leading to self-destruction, and a decided tendency appears to exist to commit the act at about the same age at which the parent died, and to use the same means; showing that the hereditary disposition is attended with a certain uniformity of action.

Education would appear to predispose to suicide, for it has been conclusively shown that more attempts occur in centres of civilization, among the best educated classes, and in cities where, through the press, pulpit, and stage, as well as through educational institutions proper, the masses of the people are better informed than those in the country, and, as a rule, have more active minds; but in whom the conditions of life are more apt to favor a spirit of discontent. Among savages suicide is comparatively rare.

Occupation appears to have a predisposing influence. Thus the trades in which the greatest number of suicides occur are shown to be those of tailors, seamstresses, laundresses, jewelers, carpenters, cooks, etc. The hardships of life attending many of these occupations may account for the number of deaths.

Wine merchants and inn-keepers make large contributions to the number of suicides, because their occupation tends to induce excess in the use of alcohol.

The liberal professions furnish about one-fifth of the total number of suicides; physicians, chemists, and druggists give a high percentage, and their occupations may be said to predispose to it by bringing them into such constant and intimate relations with poisons.

The stringency of military discipline in Germany, France, and Austria has been advanced as a reason for the high death-rate from suicide in these countries.

Morselli finds the greatest number of suicides among (1) literary and scientific men, or brain-workers generally, professors, teachers, etc.; (2) the military; (3) workers in the trades.

According to Legoyt (1856-1860), the middle classes and outcasts furnish the greatest number in France, and the same is found by Block to hold true (p. 251).

The condition of life has its influence as well, and those living solitary lives, as widowers, bachelors, divorced women, etc., are more prone to the act.

Climate and temperature in many instances undoubtedly contribute their share, but the attempts to regard them as the main cause of a high percentage of suicides in some countries have not been eminently successful. Thus the cold, rain, and fog of England have, by various writers, been regarded as conducive to self-destruction. Thus Montesquieu said, "England is the classic land of suicide;" but in Wynter we read ("The Borderland of Insanity," 1875) "Paris is the headquarters of self-destruction."

Putting aside the compliments that may be passed between these two countries, we must remember that the Esquimaux and Falkland Islanders, whose climate is incomparably more severe than either, do not kill themselves.

The influence of climate is, on the whole, not marked, but excessive heat has been known to drive men to frenzy and self-destruction. Long since it was pointed out that the hot and dry wind of the African sirocco caused delirium, madness, and many suicides.

Seasons.—In most countries the maximum of suicides is reached in May and June, when nature would seem to be most conducive to life. In Saxony and Bavaria, however, July is the favorite month.

Authorities agree that insanity increases in the summer time, and this may explain, as Wagner thought, the greater number of suicides.

Sex.—In a general way, the average of female suicides for the United States is given as from fifteen to thirty per cent. of the whole number. Liebman says three men kill themselves to every woman.

The proportion is given for Germany as under, and for England as over, twenty per cent. As accounting for this excess of male suicides it has been advanced that women have less energy, less resolution, are more governed by religious teachings, etc.

Age.—Considerable regularity is shown, in each country, in the number of suicides from year to year. From Ogle's table, as well as from those of Morselli, it is seen that, from the tenth year on, the number of cases rises steadily to between the ages of fifty-five and sixty-five years; remains almost stationary to about seventy-five, and then decreases rapidly. It is rare before fifteen, but excepting the very young, it is common to all periods of life.

The period from the twentieth to the fiftieth year has the most instances, for it is then that men pass through the most serious portion of their lives. It is then they are engaged in the battle for existence, require more comforts of life, and have most care and responsibility.

According to Ogle, one out of every 119 men who reach the age of twenty, ultimately dies by his own hand, and one out of every 312 women who have reached the age of fifteen.

Attempts upon their own lives have been made by children at as early an age as five years. Durand-Fardel found one under five, and two between eight and nine. Out of 25,760 suicides in France occurring from 1835 to 1844, he found 192 to be in persons under the age of sixteen.

According to the census of 1880, Hammond[9] says there were in the United States, during the preceding ten years, 2 suicides in children between five and ten years of age, 12 between ten and fifteen, and 66 between fifteen and twenty. He says that Collineau[10] relates the case of a boy ten years of age, who, "to make his parents angry," hanged himself on being sent back to school.

Winslow[11] reports several cases at an early age, and quotes Casper to the effect that in Berlin, from 1812 to 1821, 31 children, twelve years of age and under, committed suicide for trifling cause. Many cases at this early age appear to be similar to the emotional susceptibility of adult life.

Suicide is an act which springs from a brain constantly influenced by conditions present within the body, as well as by those of the external world, many of which we have considered as predisposing causes. We will now turn our attention to some of the internal and

Determining Causes.—Insanity with suicidal tendency is quite a common form of mental disease. I shall not enter upon a consideration of the various forms of insanity in which this tendency is present. We may find it as a monomania, or associated with a homicidal mania.

It is often by suicide that the melancholic rids himself of his imaginary woes, and the maniac escapes from the imaginary foes with which his hallucinations surround him.

There are those who claim that the act of suicide is of itself an evidence of insanity. In the maniac there is no planning, and no precautions are taken; violence is characteristic of the act, and it is as a rule accomplished quickly. Should it fail, there is a knowledge and recollection of the details. Death may accidentally result from the attempts of the maniac to escape from hallucinations, or in his efforts to free himself from restraint. This should not, properly speaking, be termed suicide, for although it is self-destruction, there is no intention or motive, and the term, as commonly used, implies a purpose.

In some insane persons there is an ever-present hallucination attended with a morbid sadness, and the act of suicide is deliberately planned and, with much precaution and calmness, carried into execution; or, if not at once successful, it will be persisted in until it is.

There is a form of anxious melancholy in which, without any cause either real or imagined, there is, as it were, an instinctive but violent desire to die; so strong, indeed, is it, that no will-power seems capable of overcoming it. The previous anxiety is lost when all preparations are made and the desired end appears near, and this sudden change to cheerfulness may give friends and attendants the cue to watch for the attempt.

As a rule, determined and deliberate attempts at suicide, with details carefully planned, indicate an unsound mind. When the attempt has failed to cause death, it is often found that insanity soon appears. In other cases the attempt itself relieves the condition which caused it, and death is no longer desired.

The flow of blood from a razor wound, Hammond says, may relieve the cerebral congestion present. In the same way, a plunge into the cold water may result in bringing the would-be suicide to a realizing sense of his desire for life rather than for death.

Others, to assure success, may tie their own hands and feet together before making the plunge, and may even attach weights to themselves, as in the recent case of a young actor who, before plunging into the Charles River, in Boston, put on a heavy coat of mail; and of a man who jumped from a Brooklyn ferryboat with lead-pipe wound round and round the body. The possible occur-

rence of such cases must be remembered in medico-legal and coroner's investigations, and not be mistaken for cases of murder. Financial ruin, famine, and pestilence following in the train of wars, etc., have often resulted in great numbers of suicides, the nervous system being over-excited.

Disease, as an inciting cause of the suicidal act, is not uncommon. The body, worn out with suffering, at last affects the mind, or the patient, believing his disease incurable, prefers to make an end of all his woes, and "fly to others which we know not of."

Statistics for Italy and France show that those affected with pellagra furnish a large percentage of suicides. Other diseases in which suicide appears to be common are those of the digestive organs, liver, etc., cancer, urinary diseases, phthisis, loss of sight, and chronic affections generally; after castration it appears also to be frequent. Suicides through physical suffering attain their maximum in the educated and cultivated classes.

Financial troubles cause the highest percentage among the working-classes, though self-destruction is often seen after reverses of fortune, losses in gambling, and financial embarrassment in the wealthy.

Alcohol is a potent cause of self-inflicted death; drunkenness, poverty, and laziness going hand in hand.

Passions.—Love, betrayed or disappointed, and jealousy are found to be a fruitful cause of suicide among students, soldiers, schoolmistresses, and servants. Explosions of rage and anger are apt to gradually increase and overcome the will-power to resist, until trivial circumstances will occasion violent outbursts, and may lead to violent acts against one's self. Hate, pride, shame, and revenge may all lead to suicide.

Other determining causes often found are domestic troubles, remorse, dishonor (as in women pregnant out of marriage), poverty, misfortune, grief, pain, and disappointment.

Occasionally regret is experienced before the act has been fully accomplished.

METHOD.—The method of securing death, and the place or scene of its execution, are influenced by the surroundings of the individual and the natural facilities afforded; but the supposition advanced by Esquirol, that the occupation governed the choice of instrument, is not always borne out by statistics. Still it is found that the choice of the soldier falls, as it in theory naturally would, upon firearms. Butchers, barbers, and shoemakers resort mostly to the knife. The favorite method varies in different countries, and although in a given locality or city the prevailing custom may change from time to time, there is a pretty constant preference for one fixed form from year to year. De Guerry[12] was the first to show a regularity in the method employed.

The rope appears to be the most common choice, second comes the water, firearms third, cutting instruments fourth, then follow jumping from a height, taking of poisons, inhalation of deadly fumes, etc.

There are two factors which, as a rule, influence the choice of the means, viz., certainty and quickness of action. Women are not so apt as men to make choice of a painless method.

There is also a difference in the means employed by women from those resorted to by men.

In Italy, for example, the men shoot themselves, and women resort to the water when weary of life; while in Prussia over half the suicides die by hanging, and women surpass the men in their tendency to kill themselves by the knife.

Poison, as a choice, appears to be increasing in favor in this country, and to be on the decline in France; in fact, the favor it receives among Anglo-Saxon suicides is shown to reach 40.8 per cent., including this country. Out of 148 cases of suicide occurring in New York in the year 1876, poison was used in 31.7 per cent.; firearms in 33.1; hanging gave 13.5; cutting wounds, 10.8; drowning, 6.8; falls from height, 3.4, and other means 0.7. Thus showing that poison and firearms were the choice, each in about one-third of the cases. This predilection on the part of the English and Irish for poisons is further shown by the following table, taken from Morselli, and giving the suicides among foreigners in New York for the year 1876.

Per 100.	English.	French.	Germans.	Irish.
Poisoning	46.1	25.0	28.9	52.4
Hanging	....	12.5	17.4	4.8
Asphyxia and drowning	....	....	5.7	9.6
Gunshot wounds	15.4	50.0	35 0	4.8
Cutting and stabbing	30.8	....	7.2	9.5
Falls from height	7.7	12.5	5.8	18.9
Total	100.0	100 0	100.0	100.0

Of the 39 cases of suicide which I have found reported in the daily newspapers of this city during the past fifty days, the greatest number (12) was by shooting, and the next highest (7) by taking poison. The poison chosen is usually the one easily obtained and of known efficacy.

In England the order of choice is prussic acid, cyanide of potassium, laudanum, oxalic acid, arsenic, strychnine, vermin killer, oil of bitter almonds.

In New York a vermin poison known as Rough on Rats, and supposed to contain arsenic, has been so much employed of late that the authorities have been asked to place restrictions upon its sale.

Drowning as a means decreases as the north is approached; the colder the water, the less its attractions.

Devergie found that in Paris, from 1827 to 1836, drowning, together with asphyxia by charcoal fumes, held the second place, but in 1851 Trébuchet placed asphyxia at the head of the list. This latter mode of death has spread rapidly over Europe and increased in fashion in Paris. The reasons for this are that it affords the most painless and agreeable form of death, and, strange as it may appear, man's vanity extends beyond the gates of death, and the suicide desires the body to present a good appearance after the breath has left it, and knows that there is usually no disfigurement from charcoal fumes.

Only the other day, the papers contained an account of a "wholesale charcoaling," in which a father, mother, and two children sought death in this way, preferring this mode of death to starvation. When heredity is a factor in the case, the method of exit from the world is apt to be the same as that employed by the ancestor.

Winslow says that one manner of death having been conceived, the man bent on suicide will wait a long time until he can carry out his particular plans. We, however, often see a man who has failed in one way take the first opportunity to secure death in another. Maniacs are most apt to throw themselves from a height, and it is often difficult to say whether one who has fallen from a window did so in simply making an attempt to escape imaginary enemies, mistaking the window for a door, or possibly walked out without any knowledge of the act, or was conscious of the attempt. Some inflict wounds upon themselves, or severely injure the head by pounding it against the wall, impelled by their pains to seek this means of gaining relief. Melancholics often hear a voice urging them to take their lives, and this "voice" at times suggests the means.

Place.—Much ceremony attends the act in some individuals, and publicity is sought. This is often done when revenge is intended. Usually, however, suicides occur in privacy, and it is not uncommon for a man to retire to a concealed and unfrequented spot to carry out his object.

Particular places may become, as it were, fashionable for a time, in the suicidal world. Thus, one year, in Paris, the Arc de Triomphe, another Notre Dame steeple, and another one of the bridges, will be the favorite leap. The Milan Cathedral, St. Peter's at Rome, and the Campanile at Florence, have all in turn had their epidemics, so to speak.

Esquirol[13] relates a very remarkable method which was employed in a case reported by Dr. Ruggieri,[14] an Italian, which shows what an amount of self-inflicted torture will be endured. A shoemaker in Naples, who had the year before castrated himself and thrown the geni-

tals from the window, after making a good recovery, conceived the idea that God had commanded him to suffer on the cross. He passed two years in perfecting his plans, which were so well carried out that one morning he was found with hands and feet securely nailed to a cross, with a stab wound in the left side, hanging out of his bedroom window. He had constructed the cross and attached it by ropes in such a way that after crucifying himself he could, by motions of the body, cause it to slip from the window. When rescued he was delirious, and though recovering from his wounds, he exhausted himself by fasting and died.

A novel method has just been introduced in this country by an anarchist, of exploding a dynamite cartridge in the mouth, bearing out Esquirol's claim, that the instrument chosen was apt to be the one which the suicide used professionally.

Time.—The time of day most favorable to acts of self-destruction appears to be between the hours of six and twelve in the morning. This preference for the early part of the day extends to the other divisions of time, for it has been found that more suicides occur in the fore-part of the week and the first half of the month than in the latter parts.

SYMPTOMS.—It is questionable whether we can say that there are any actual symptoms by which an act of suicide can be predicted. In insanity, and especially in melancholia, an attempt must always be watched for.

In some cases a man, who has been previously healthy, will complain of pain in the epigastrium, of heaviness in the head, will become quiet, listless, lose all ambition, refuse to work or attend to his usual vocations; the habits are changed, and intoxication may be indulged in. There may be scarcely any other symptoms until he tries to cut the thread of life. Weariness of life is often complained of, but Esquirol says he has never seen any attempt because of this *tædium vitæ* alone.

Some individuals predict that they will some day kill themselves and eventually do, but as a rule the one who threatens the act rarely commits it.

In some cases it may be discovered that preparations are being made for death, associated with a sadness of expression and an uneasiness of action. In melancholia the opposite condition may prevail just before the attempt, when all the plans are laid. The skin of suicides has been said to assume a yellow tinge and the features to become shrivelled, giving a changed appearance at the same time that a change is noticed in the actions.

Anæsthesia is a marked symptom at the actual moment of the attempt in many cases, and it is said that after the skin is cut the pain in cutting the throat is not at all severe. This accounts for the little complaint or appearance of pain in cases which, it would appear, must have been attended with torture.

DIAGNOSIS is important in a medico-legal sense, as we have seen that few signs or symptoms of value precede the act. A knowledge of previous attempts will aid us, and at times a hint may be given by some word of the individual, or by an ante-mortem letter.

If the attempt has failed the fact may be acknowledged; if death has resulted writings are to be looked for. The body is to be examined for lesions, especially in the vital regions. The direction of bullet and penetrating stab wounds is to be carefully noted, and the existence or absence of powder marks upon the skin, and wadding, pieces of clothing, etc., within the wound. If death has resulted from a sharp weapon, signs of violence must be looked for upon the body and in its surroundings. The employment of a razor, although favoring a theory of suicide, is not to be regarded as conclusive, because in this country it is quite a favorite weapon with the negro race. If the razor can be shown to belong to the individual, the suicide theory is strengthened.

If poison has been taken, a bottle or paper which has contained it may be discovered near the scene. Though most men found hanging are suicides, the possibilities of lynching and of hanging a dead body to hide a crime must be remembered. In bodies found in the water, great care must be exercised in giving true significance to wounds, and determining whether they were inflicted before death. The fact that the limbs are tied has not great weight, for the suicide might have thought thus to assure success, and even have attached weights to the body.

Pathological lesions found on autopsy shed but little light on the subject of suicide.

PROPHYLAXIS.—Cannot something be done, we instinctively ask, to prevent so great a number of human beings from committing so heinous an act? Something at least to prevent the ever-constant increase? The solution of the problem must lie largely in the better care of the insane, and earlier and more scientific treatment of mental diseases. Hospitals properly equipped for the treatment, supervision, and restraint of the mentally weak and infirm, and the disappearance of the popular prejudice against insane asylums, will do much to decrease the number of suicides in this large class.

Legislation.—In epidemic suicide and in alarming increase of the act, it has been found necessary to enforce stringent laws against the bodies, property, and families of the suicide at various periods of the world's history, and at times with some apparent success.

Laws were established in regard to suicide at a very early day. Zeno's motto, which was such a favorite phrase of the Stoics, "*Mori licet cui vivere non placet,*" was found not to have an application to the individual whose act caused injury to others and loss to the state. It was opposed to the teaching of the Bible, which says "Thou shalt not kill."

Esquirol thinks some threatening law against the individual should be enforced with reference to the social usages of the people of each particular country. He says comminatory laws have caused suicide to cease in Egypt and Miletus.

Legislation, though not powerful to accomplish much, should nevertheless exist. It will undoubtedly deter a few, and this alone will prove its usefulness.

The attempt at suicide is punishable in New York State by five years imprisonment, according to existing laws recently enacted.

The confiscation of property and denial of the right of burial, formerly practised in France, have, of late years, been stricken from the Code.

Formerly, in England, the body of a suicide was treated with ignominy, buried in the highway, and transfixed by a stake. When this law was abolished, the body could still only be buried at night and without religious rites. The Canons of the Roman Catholic Church still forbid the burial of a suicide in consecrated ground.

The laws of antiquity, severe as they were upon the family, name, and possessions of the individual, had but slight effect in repressing suicide, as they naturally would have in the insane, who contribute most largely. In some countries the bodies of all suicides are given for dissection.

The public press has it in its power to favor an increase in suicide by publishing, with minute details, descriptions of all suicides, thus exciting depraved tastes, pampering to the vicious, and putting ideas regarding the act into the minds of nervously weak and predisposed persons. Fortunately, this tendency is much less marked than at a former period, but the danger should be constantly pointed out and guarded against when suicides become at all frequent in a community.

Silence is the antidote for this form of nervous, imitative suicide, as Moreau has aptly and truly said.

TREATMENT.—When a tendency to self-destruction has been discovered, moral treatment may be of much benefit. Kindness, cheerful attention, and society, and the assurance of aid and support may brighten hope. Argument and sympathy have never done good. When an individual threatens to kill himself, the best treatment is probably to tell him to go ahead and do it. This usually results in a cessation of the threats.

Those mentally afflicted should be placed in institutions, and it has been recommended that all having suicidal tendency be placed together, at least at night, and this plan is carried out in many of our institutions.

Tonics and sedatives are usually called for, and remedies suited to the physical derangement, whatever that may be.

SULPHIDES. Sulphides of four metallic bases occur among medicines, namely, sulphides of *mercury*, *antimony*, *potassium*, and *calcium*. Of these, the sulphides of mercury and antimony are medicinally not specifically peculiar, and will be found discussed under the titles of the several metals. The sulphides of the other two bases exhibit marked properties, evidently due to the sulphur of their composition, and form thus a distinct group of medicines. The common characteristics are the possession of, physically, an alkaline reaction, a disagreeable smell, and an alkaline and offensive sulphuretted taste; physiologically, quite intense, irritant properties, and a special obnoxiousness to animal and vegetable skin parasites; and, therapeutically, a local healing influence over many skin diseases in their chronic stage, and, given internally, an uncertain tendency to abate chronic glandular, or cutaneous, or arthritic disease, and to control or repress suppuration. In full dose too long continued, the compounds tend to impair general nutrition, leading to emaciation and muscular weakness. Following are in detail the pharmaceutical preparations containing the sulphides in question, with their special properties and uses:

Potassa Sulphurata: *Sulphurated Potassa.*—This is an officinal preparation of the United States Pharmacopœia, made by heating in a covered crucible to melting a mixture of dried potassic carbonate and sublimed sulphur. The product solidifies upon cooling, and is then broken into pieces and put up in well-stopped bottles of hard glass. Products obtained by the foregoing general process are commonly called, generically, *hepar sulphuris* (liver of sulphur), the name being expressive of the color. Such products are composite bodies, but the composition varies according to the degree of heat to which the mixture of potassic carbonate and sulphur has been subjected in the preparation. By the comparatively low heat directed in the United States pharmacopœial process, the product is probably a mixture of potassic hyposulphite and trisulphide ($K_2S_2O_3 + 2K_2S_3$). At a higher heat, such as is used in the British pharmacopœial process, the hyposulphite first formed splits into potassic sulphate and pentasulphide. Sulphurated potassa appears in "irregular pieces of a liver-brown color when freshly prepared, turning gradually to greenish-yellow or brownish-yellow, having a faint, disagreeable odor, a bitter, alkaline, repulsive taste, and an alkaline reaction. Soluble in about two parts of water at 15° C. (59° F.), with the exception of a small residue; partly soluble in alcohol, the latter leaving undissolved the accompanying impurities. The aqueous solution has an orange-yellow color, and exhales the odor of hydrosulphuric acid. The latter is abundantly evolved on the addition of hydrochloric acid, while, at the same time, sulphur is deposited" (U. S. Ph.). The product should contain at least fifty-six per cent. of the potassic sulphide. It is decomposed by mineral acids, and by most solutions of metallic salts.

Sulphurated potassa possesses the general properties detailed above; it is violently irritant, even to corrosiveness, and overdosage may easily kill by excessive gastro-intestinal irritation. The medicine is used, locally, to kill parasites, and to favor the healing of skin disease or the abatement of rheumatic or gouty troubles, and, internally, to assist in the two latter-named operations. The parasiticide action is utilized mainly for the destruction of the itch-insect, for which purpose this compound is exceedingly efficacious. The preparation is applied locally, in the form of ointment, lotion, or general bath. For an ointment of proper average strength, sulphurated potassa may be mixed with lard in the proportion of six per cent. of the former; for a lotion, an aqueous solution ranging from three to six per cent. in strength may be used; and, for a bath, about 125.00 Gm. (four ounces) may be dissolved in about 120 litres of water (about thirty gallons). Concentrated applications should never be made, because of the sharp irritation which would thereby certainly be set up. Baths containing sulphurated potassa (commonly spoken of as *sulphur-baths*), besides their foregoing use, are sometimes employed in the treatment of chronic lead-poisoning, because of the finding that patients suffering from lead-contamination show upon their skins, after immersion in a sulphur-bath, a dark discoloration, as from the forming there of lead sulphide. The inference is that the sulphur in some mysterious way coaxes the lead out of the system through the skin-emunctories, in order to satisfy its chemical longing for a union with the metal. Sulphur-baths are administered warm or hot, and of a duration from half an hour to two or three hours. They are apt, particularly when protracted, to produce a good deal of irritation of the skin, even to the development of a papular or vesicular eruption. These baths should be prepared in wooden tubs. For internal giving, the dose of sulphurated potassa ranges from 0.12 to 0.40 Gm. (two to six grains), several times a day, given in pill, or in some aromatized syrup.

Calx Sulphurata: *Sulphurated Lime.*—The preparation thus named in the United States Pharmacopœia is what is commonly, but incorrectly, called *sulphide of calcium*. It is a mixture in varying proportions of calcic sulphide and calcic sulphate, but should contain at least thirty-six per cent. of absolute calcic sulphide—the salt which gives the substance its medicinal activity. Sulphurated lime is made, by the process directed in the United States Pharmacopœia, by heating to a low red heat in a closed crucible a mixture of lime ("quick-lime") and sulphur. The product, after cooling, is pulverized, and at once put up in small glass-stoppered phials. It appears as "a grayish-white or yellowish-white powder, gradually altered by exposure to air, exhaling a faint odor of hydrosulphuric acid, having an

offensive, alkaline taste, and an alkaline reaction. Very slightly soluble in water, and insoluble in alcohol" (U. S. Ph.).

Sulphurated lime, like sulphurated potassa, has the general properties of the alkaline sulphides, as already detailed. It is powerfully irritant, even medicinal doses being apt to upset the stomach. And it is a disagreeable medicine for internal taking, also, because of its giving rise to eructations of sulphuretted gases. The preparation has been used, locally, principally as a depilatory, the powder being applied directly to the hairy area, and after fifteen minutes the part gone over with a wet sponge. Medicine and hairs then come away together. Internally, sulphurated lime has rather recently acquired a reputation as tending to control suppurations, the discharge lessening in quantity, and their unhealthy pus acquiring a healthier character under the influence of the medicine. Given between times in recurring suppurations, as in recurring crops of boils, it is also held to abate the frequency and severity of the attacks. The dose of sulphurated lime ranges from 0.003 to 0.006 Gm. (one-twentieth to one-tenth of a grain), several times a day, or even hourly, given most conveniently in trituration with sugar of milk. *Edward Curtis.*

SULPHITES AND "HYPOSULPHITES" (Thiosulphates). I. General Medicinal Properties of Sulphites and "Hyposulphites."—A number of sulphites and "hyposulphites" being used in medicine because of a virtue which they are considered to derive, in common, from their acid radicles, such salts form a distinct group of medicines, which it is convenient to discuss under a single heading. The class-characteristics are as follows: The salts are soluble in water, have a combined saline and sulphurous flavor, and are, in physiological operation, locally bland and constitutionally innocuous. From a medicinal point of view, their most important reaction is that in the presence of stronger acids they are decomposed, with the evolution of sulphurous acid. Given medicinally, they are thought to undergo this change in the stomach through the agency of the free acid of the gastric juice. The decomposition is said to be slower with "hyposulphites" than with sulphites. As a secondary result of the chemical change, sulphates are formed, such being the combination in which the base reappears in the urine when a sulphite or "hyposulphite" is swallowed in ordinary dosage. Medicinally, these salts are employed with the single view of obtaining by their means the germicide and antiseptic action of sulphurous acid. But in this connection it must be carefully borne in mind that sulphites and "hyposulphites," while maintaining their chemical composition as such, have been experimentally proved to be practically devoid of either germicide or antiseptic power.[1] They can, therefore, even theoretically, be of avail in this line only under circumstances determining their decomposition and the evolution thereby of sulphurous acid. Such reaction may take place in the stomach, but is seemingly impossible in the blood, and with the inference naturally following from these premises clinical experience is in accord. For these salts have been vaunted in the treatment of pyrosis and sarcinæ, and their employment has proved fairly efficacious; but they have been even more strenuously advocated for the treatment of constitutional diseases assumed to be caused by infection of living organisms (Nolli), and have, in the hands of the majority of the profession at least, signally failed. The salts have also been used, with variously reported success, as lotions for the cure of parasitic skin disease, or for the abatement of the pain of chilblains, sprains, etc.—applications in which it is certainly doubtful if they exert any specific influence.

II. The medicinally used Sulphites and "Hyposulphites."—The salts of this category are the normal sulphite of *potassium*, the normal and acid sulphite, respectively, of *sodium*, the sulphite of *magnesium*, and the normal thiosulphate of *sodium* (commonly called *hyposulphite*).

Normal Potassic Sulphite, $K_2SO_3.2H_2O$.—The salt is officinal in the United States Pharmacopœia under the title *Potassii Sulphis*, Sulphite of Potassium. It occurs as "white, opaque, obliquely rhombic, octahedral crystals, or a crystalline powder, somewhat deliquescent, odorless, having a bitter, saline, and sulphurous taste, and a neutral or feebly alkaline reaction. Soluble in four parts of water at 15° C. (59° F.), and in five parts of boiling water; only sparingly soluble in alcohol. When gently heated, the salt loses its water of crystallization (18.5 per cent.); at a red heat it is decomposed and leaves a residue of an alkaline reaction" (U. S. Ph.). The salt should be kept in well-stopped bottles.

Potassic sulphite may be used locally in twelve per cent. aqueous solution, or given internally in doses ranging from 1.00 to 4.00 Gm. (fifteen to sixty grains), three or four times a day.

Normal Sodic Sulphite, $Na_2SO_3.7H_2O$.—The salt is officinal in the United States Pharmacopœia as *Sodii Sulphis*, Sulphite of Sodium. It occurs in "colorless, transparent, monoclinic prisms, efflorescent in dry air, odorless, having a cooling, saline, and sulphurous taste, and a neutral or feebly alkaline reaction. Soluble in four parts of water at 15° C. (59° F.), and in 0.9 part of boiling water; only sparingly soluble in alcohol. When gently heated, the salt melts, then loses its water (fifty per cent.), and at a red heat it is decomposed and leaves a residue having an alkaline reaction. A fragment of the salt imparts to a non-luminous flame an intense yellow color, not appearing more than transiently red when observed through a blue glass" (U. S. Ph.). The salt should be kept in well-stopped bottles, in a cool place.

Sodic sulphite may be used in same manner and dose as the potassic salt.

Acid Sodic Sulphite, $NaHSO_3$.—The salt is officinal in the United States Pharmacopœia as *Sodii Bisulphis*, Bisulphite of Sodium. It occurs in "opaque, prismatic crystals, or a crystalline or granular powder, slowly oxidized, and losing sulphurous acid on exposure to air, having a faint, sulphurous odor, a disagreeable, sulphurous taste, and an acid reaction. Soluble in four parts of water, and in seventy-two parts of alcohol at 15° C. (59° F.); in two parts of boiling water, and in forty-nine parts of boiling alcohol. When strongly heated, the salt decrepitates, and is converted into sulphur and sulphate of sodium. A small fragment of the salt imparts to a non-luminous flame an intense yellow color, not appearing more than transiently red when observed through a blue glass" (U. S. Ph.). This salt must be kept in well-stopped bottles.

This sulphite is less stable than the normal sodic salt, and more disagreeable to taste. In other respects it is similar.

Magnesic Sulphite, $MgSO_3.6H_2O$.—The salt is officinal in the United States Pharmacopœia as *Magnesii Sulphis*, Sulphite of Magnesium. It occurs as a "white, crystalline powder, gradually becoming oxidized on exposure to air, odorless, having a slightly bitter, somewhat sulphurous taste, and a neutral or slightly alkaline reaction. Soluble in twenty parts of water at 15° C. (59° F.), and in nineteen parts of boiling water; insoluble in alcohol. When heated to 200° C. (392° F.), the salt loses its water of crystallization (50.9 per cent.), and is converted into magnesia and anhydrous sulphate of magnesium" (U. S. Ph.). The salt should be kept in well-stopped bottles.

Magnesic sulphite is the least unpleasant of the sulphites to taste. Uses and dose as with the potassic salt.

Normal Sodic Thiosulphate ("Hyposulphite"), $Na_2S_2O_3.5H_2O$.—The salt is officinal in the United States Pharmacopœia under its former chemical title of *Sodii Hyposulphis*, Hyposulphite of Sodium. The present confusion in the use of the term *hyposulphite* arises from the fact that before the discovery by Schützenberger of what is now, and properly, called hyposulphurous acid—namely, the body H_2SO_2—the name in question was applied to thiosulphuric acid ($H_2S_2O_3$). Hence it comes about that though a true sodic hyposulphite is known, the salt that passes current by that name is not a hyposulphite, but a thiosulphate. The old title, however, is so firmly fixed by long and popular usage that it has been retained by

the United States Pharmacopœia, and is the title by which the salt is universally known as a medicine. Sodic "hypo-sulphite" occurs as "large, colorless, transparent, monoclinic prisms or plates, efflorescent in dry air, odorless, having a cooling, somewhat bitter and sulphurous taste, and a neutral or faintly alkaline reaction. Soluble in 1.5 part of water at 15° C. (59° F.), and in 0.5 part of boiling water, in the latter case with partial decomposition; insoluble in alcohol. When rapidly heated to about 50° C. (122° F.), the salt melts; when slowly heated until it is effloresced, and afterward to 100° C. (212° F.), it loses all its water (36.3 per cent.), and at a low red heat it is decomposed. A fragment of the salt imparts to a non-luminous flame an intense yellow color, not appearing more than transiently red when observed through a blue glass" (U. S. Ph.). The salt must be kept in well-stopped bottles.

Sodic "hyposulphite" is more stable than the sulphites, undergoing decomposition by acids less easily. In properties, uses, and modes of administration it resembles potassic sulphite. The internal dose is generally from 1.00 to 1.30 Gm. (fifteen to twenty grains).

Edward Curtis.

[1] Sternberg: American Journal of the Medical Sciences, April, 1883, p. 321.

SULPHOCARBOLATES: *Phenolsulphonates.* Carbolic acid (*phenol*), added to strong sulphuric acid, dissolves with the formation of the acid body, $C_6H_4(OH).SO_3H$, termed *phenolsulphonic acid* by the chemist, but commonly known as *sulphocarbolic acid.* Sulphocarbolic acid unites with bases to the formation of salts, and in these salts it was hoped there might be found substances which would retain the therapeutic powers of carbolic acid while free from the poisonous properties of that body. So far as observation has gone, however, this hope does not seem to have been realized. A single salt of sulphocarbolic acid is officinal in the United States Pharmacopœia, as follows:

SODII SULPHOCARBOLAS, *Sulphocarbolate of Sodium,* $NaC_6H_5SO_4.2H_2O$, U. S. Ph.—This salt is described as "colorless, transparent, rhombic prisms, permanent in the air, odorless or nearly so, having a cooling, saline, somewhat bitter taste, and a neutral reaction. Soluble in 5 parts of water, and in 132 parts of alcohol at 15° C. (59° F.); in 0.7 part of boiling water, and in 10 parts of boiling alcohol. When heated, the salt loses its water and becomes a white powder" (U. S. Ph.). This is a bland salt, producing but little constitutional disturbance in ordinary medicinal doses beyond some lightness of the head. It has been prescribed in doses ranging from 0.65 to 2.00 Gm. (from ten to thirty grains) for the purpose of constitutional antisepsis in so-called zymotic diseases, but without striking results. *Edward Curtis.*

SULPHO-SALINE SPRINGS. *Location and Post Office,* Cincinnati, Hamilton County, O.

ANALYSIS (E. S. Wayne).—One pint contains:

	Grains.
Carbonate of magnesia	1.141
Carbonate of lime	2.417
Chloride of potassium	0.493
Chloride of sodium	66.846
Chloride of magnesium	2.157
Chloride of calcium	2.773
Chloride of lithium	0.029
Sulphate of potassa	0.287
Sulphate of lime	3.650
Phosphate of soda	0.167
Iodide of magnesium	0.037
Bromide of magnesium	0.049
Oxide of iron	0.053
Silica	0.098
Total	80.197
Gas.	Cub. in.
Carbonic acid	1.57
Sulphuretted hydrogen	0.91

THERAPEUTIC PROPERTIES.—This well is a strong sulpho-saline one, and has a local reputation as a cathartic and alterative. As warm baths, the water is very useful in chronic skin diseases, and rheumatism.

This water flows from an artesian well (2,408 feet deep), bored for the purpose of supplying a brewery. Being unfit, on account of its mineral properties, for that purpose, it has been utilized as a mineral spring, and a large bath-house has been erected, furnished with every convenience. The water has a temperature of 62° F. and is abundant. *G. B. F.*

SULPHUR. Sulphur is used in medicine in the condition of fine powder, three styles of which are officinal in the U. S. Pharmacopœia, as follows:

SULPHUR SUBLIMATUM, *Sublimed Sulphur.*—This preparation, commonly called *flowers of sulphur,* is crude sulphur purified by distillation in an apparatus so arranged that the vaporized sulphur shall condense in the form of a powder upon the walls of the receiving chamber. Sublimed sulphur is a "fine, citron-yellow powder, of a slight, characteristic odor, and generally of a faintly acid taste, and an acid reaction. It is insoluble in water or alcohol. When ignited, it burns with a blue flame, forming sulphurous acid gas, and leaving no residue, or only a trace" (U. S. Ph.). Sublimed sulphur always contains a little sulphuric acid, whereby it is unfitted for internal medicinal use.

Sulphur Lotum, Washed Sulphur.—This preparation is simply sublimed sulphur freed from contaminating sulphuric acid. The sulphur is digested for three days with diluted water of ammonia, by which process the sulphuric acid is fixed as ammonic sulphate, and the mass is then thoroughly washed with water upon a muslin strainer. The ammonic sulphate is thus washed away, and the purified sulphur is finally dried at a gentle heat, and passed through a No. 30 sieve. Washed sulphur is "a fine, citron-yellow powder, odorless and almost tasteless, insoluble in water or alcohol, but completely soluble in a boiling solution of soda, or in disulphide of carbon. When heated to 115° C. (239° F.), washed sulphur melts, and at a higher temperature it is volatilized, without leaving more than a trace of residue. Water agitated with it should not redden blue litmus paper (abs. of free acid.)" (U. S. Ph.). When derived from a sulphur originally obtained from metallic sulphides, washed sulphur may contain the very dangerously contaminating substance, arsenic, in the form of the trioxide or trisulphide of that element. Proof of absence of arsenic is afforded by digesting a sample of washed sulphur with two parts of ammonia, filtering, and finding the filtrate unaffected by super-saturation with hydrochloric acid, and not precipitated by passing through it a stream of hydrogen sulphide.

SULPHUR PRECIPITATUM, *Precipitated Sulphur.*—This preparation, formerly known as *milk of sulphur,* is an exceedingly fine powder of sulphur, gotten by precipitating with diluted hydrochloric acid a solution of sulphur salts of calcium, obtained by mixing sublimed sulphur and slaked lime with water. The sulphur, after precipitation, is collected upon a strainer, thoroughly washed with water, and dried at a gentle heat. Precipitated sulphur is "a very fine, yellowish-white, amorphous powder, odorless and almost tasteless, insoluble in water or in alcohol, but completely soluble in a boiling solution of soda or in disulphide of carbon. By heat it is completely volatilized" (U. S. Ph.). Precipitated sulphur should stand the same tests for absence of free acid and of contaminating arsenic as washed sulphur (see above). This variety of sulphur-powder differs from the foregoing in being lighter in color, and of finer particles. From the latter fact it derives the advantages of greater smoothness and readiness of mixing with fluids; but, to offset, it has the disadvantage of tending to develop an acid upon keeping.

Sulphur, as the pharmacopœial descriptions say, is insoluble in water, and practically so in alcohol, but dissolves in varying proportions in solutions of the alkalies and in oils, fixed and volatile. Because of its insolubility in aqueous fluids, sulphur is practically devoid of physiological activity while under its own form, but, when rubbed in ointment upon the skin, or when taken internally, a feebly irritant action appears, presumably

due to a sulphide formed in small quantity by the chemicals present in the secretions of the part. What little of an internally taken dose of sulphur is absorbed is also probably in the condition of a sulphide, and the constitutional effects that follow are a feeble reflex of those of the alkaline sulphides (see Sulphides). In single, considerable dose the local irritation displayed by sulphur determines increased intestinal activity, showing itself by relaxation of the bowels, but this with but little increase of secretion. The stools are therefore generally composed of solid or semi-solid fecal matter, and the operation of the medicine is mild and slow, the call to stool rarely occurring until from six to eight hours after the taking of the sulphur. If habitually used as a laxative, sulphur may induce a low catarrh of the alimentary tract. A disagreeable feature of its internal taking for any purpose is the tendency to the generation of flatus, offensive from the presence of sulphuretted gases.

The therapeutic applications of sulphur are as follows: By some it is given internally as a means of getting the constitutional effects of the sulphides in constitutional diseases, but by the majority of practitioners the internal use is in laxative dose only, for a laxative effect. Such dose is from 4.00 to 12.00 Gm. (one to three drachms), the washed or precipitated preparations being selected, and the powder mixed with molasses or diffused in milk for the taking. Externally, ointments containing sulphur are a good deal used as mildly irritant applications in skin diseases generally, and, specifically, as efficient parasiticidal dressings in itch. The pharmaceutical preparations of the United States Pharmacopœia are as follows:

Unguentum Sulphuris, Sulphur Ointment.—This preparation is compounded of thirty parts of sublimed sulphur and seventy of benzoinated lard, thoroughly incorporated. It may be applied without dilution, and is a very commonly used ointment for the treatment of the itch. It has a disagreeable sulphuretted smell, which may be to a certain degree masked by the addition of a little of some odoriferous volatile oil.

Unguentum Sulphuris Alkalinum, Alkaline Sulphur Ointment.—Washed sulphur and half the quantity of potassic carbonate are rubbed together with a little water, and the whole then thoroughly mixed with benzoinated lard. The finished ointment contains twenty per cent. of sulphur. In this preparation the alkali of the potassic compound probably determines a more rapid solution of the sulphur, so that the ointment is more prompt and thorough in action than the simple one just described, but it is for that reason more likely to provoke untoward irritation. *Edward Curtis.*

SULPHUR DIOXIDE (formula SO_2). This compound, commonly miscalled *sulphurous acid gas*, is the product of the combustion of sulphur in air. It is a colorless gas, of a well-known characteristic "sulphurous" odor, and is both offensive to the nostrils and intensely irritant to the larynx. Even the fumes of a single burning sulphur match-head easily excite coughing, and air highly charged with the gas is fatal to life. Sulphur dioxide dissolves freely in water—in one-fiftieth of its volume at ordinary temperatures—forming in the process of solution an acid body, *sulphurous acid* proper (H_2SO_3) (see Sulphurous Acid).

The medicinally valuable property of sulphur dioxide is its peculiar noxiousness to the vitality of disease-germs—a germicidal potency in which this compound, among gases, is rivalled only by chlorine and the vapors, respectively, of bromine and of iodine. And considering the cheapness and ease with which, by the simple combustion of sulphur, sulphur dioxide can be obtained, the gas leads the list of practically available and really efficient aërial disinfectants. Yet in its application the inherent uncertainties in the general method of aërial disinfection must never be forgotten. Could we be certain that every disease-germ present in a chamber would be fully exposed to the action of the disinfectant gas, then we might rely with corresponding fulness upon the disinfection thus attained; but when we bethink us how easily these germs, microscopic in size, may be safely fortified against assaults of a gas by lodgement in cracks and crannies of furniture and fabrics, then we cannot but realize the important truth, that even the most thorough so-called disinfection by this, the most potent of the practically available aërial disinfectants, is at best but an unreliable procedure. In this connection the strong and offensive smell of sulphur dioxide is a distinct advantage, since, after fumigation by the gas, a chamber and all articles therein must be thoroughly aired, and thus additionally disinfected, before the human nose will permit of their resumed use.

For the determination of the exact germicidal power of sulphur dioxide, very careful experiments were made by Sternberg,[1] by submitting vaccine virus, moistened with glycerin on the one hand, and dried upon ivory-points upon the other, to the action, in a closed chamber, of air charged with varying percentages of sulphur dioxide, the exposure ranging from six to twelve hours. After exposure the virus, or the charged ivory-points, were used for vaccination side by side with some of the same sample of virus which had not been exposed to the germicide. The general results were that, in the case of moist lymph, destruction of infective power followed a twelve-hour exposure to air charged with a proportion of sulphur dioxide such as would be produced by burning three-quarters of a grain of sulphur for each cubic foot of air; and, in the case of the dried virus, similar results followed with an impregnation equivalent to the combustion, per cubic foot of air, of three grains of sulphur. These results accord with common experience, and teach that at least a one per cent. impregnation of air with sulphur dioxide will ordinarily be required to sterilize floating germs.

For the practical application of sulphur dioxide as an aërial disinfectant, the gas is most easily and cheaply obtained by burning sulphur, and in calculating the quantity of sulphur required it is obviously wisest to err very far on the safe side. A good rule is therefore to allow from two to three pounds for each one thousand cubic feet of chamber to be disinfected. The strength of fumes thus generated being vastly in excess of what is respirable, the procedure is only possible in vacated rooms. In a chamber to be operated upon, therefore, all living creatures must be removed, and every possible outlet for the gas, such as door-ways, windows, and chimneys, must be closed, and even cracks and key-holes should be stopped with cotton or pasted over with paper. Then all articles needing disinfection must be thoroughly exposed on all sides to free access of the gas—bureau-drawers being opened, carpets, curtains, and blankets hung over lines across the room, and mattresses ripped open and the hair loosely strewn on the floor. The proper quantity of sulphur, in the form of sublimed sulphur, is then best mixed with one-fortieth of its weight of powdered charcoal, to secure readier combustion, and put into an iron pot, or upon a metal plate resting upon the legs of a half-open pair of tongs set across a wash-tub half full of water. By these precautions all danger of accidental setting of the floor on fire is avoided. A single door being left unsealed, the operator fires the sulphur by a live coal or a teaspoonful of flaming alcohol, and immediately retires, closing and sealing the door behind him. The sulphur is left to burn itself out, and next day the chamber is cautiously entered, the windows thrown open, and all articles thoroughly aired. It is possible also to generate sulphur dioxide by burning carbon disulphide in a specially constructed lamp, but from the great inflammability of that compound the procedure is not altogether safe, and presents no advantages over the simple method by the combustion of sulphur.

Edward Curtis.

[1] American Journal of the Medical Sciences, April, 1883.

SULPHUR IODIDE. Under the title *Sulphuris Iodidum*, Iodide of Sulphur, the United States Pharmacopœia recognizes a preparation made by fusing by heat a mixture of one part of washed sulphur and four parts of iodine. The fused mass, after cooling, is broken into pieces and

kept in glass-stoppered bottles. The article is described as "a grayish-black solid, generally in pieces, having a radiated, crystalline appearance, the characteristic odor of iodine, a somewhat acrid taste, and a faintly acid reaction. It is insoluble in water, but very soluble in disulphide of carbon; also soluble in about sixty parts of glycerin. Alcohol and ether dissolve out all the iodine, leaving the sulphur. When exposed to the air it gradually loses iodine. On being heated, it sublimes, the first part of the sublimate consisting of iodine, and the subsequent portion containing both iodine and sulphur. On continued heating it is volatilized, without leaving more than a trace of residue. If 100 parts of Iodide of Sulphur be thoroughly boiled with water, all the iodine will escape, and about 20 parts of sulphur will remain" (U. S. Ph.).

This substance is differently regarded by chemists, some considering it a definite compound, corresponding to the formula I_2S_2, and others thinking it more probably a mere physical mixture. If a true chemical compound, it is one of exceptional instability, as the foregoing narration of its properties makes evident. To the therapeutist it presents itself practically as a joint representative of free sulphur and free iodine. It has occasionally been given internally for the purposes for which iodine is so administered, but the commoner employment is external as a gently irritant, iodized application in various skin diseases. It is best applied in the form of ointment made with lard, containing the sulphur iodide in the proportion of about eight per cent.

Edward Curtis.

SULPHURIC ACID: Oil of Vitriol, H_2SO_4. This well-known acid is officinal in the United States Pharmacopœia under the title *Acidum Sulphuricum*, Sulphuric Acid, and is defined to be "a liquid, composed of not less than ninety-six per cent. of absolute sulphuric acid, and not more than four per cent. of water" (U. S. Ph.). Sulphuric acid is a heavy liquid of an oily appearance, colorless when newly made, but apt to acquire a smoky hue upon keeping. The specific gravity varies in different samples, but a gravity of 1.840 is recognized as standard by the U. S. Pharmacopœia. The acid has an intense affinity for water. Mixed with that fluid, it unites therewith with the evolution of considerable heat and with a contraction of volume, forming a clear solution. By reason of the same affinity, many organic bodies are decomposed upon treatment with sulphuric acid, the acid abstracting from their molecule the elements of water. Thus, by dehydration, oxalic acid is chemically broken up, alcohol is converted into ethylene gas (C_2H_4), wood and sugar are blackened, and textile fabrics and animal tissues are destroyed. Sulphuric acid, if diluted, also attacks most of the common metals, the prominent exceptions being gold, platinum, and iridium. Certain of the metals, such as copper, mercury, antimony, bismuth, tin, lead, and silver are also acted upon by the concentrated acid, if the same be heated.

Upon the living animal system strong sulphuric acid acts purely as a powerful caustic. Its action is a spreading one, and the sloughs have a dusky or blackish hue, quite different in color from the yellow sloughs produced by nitric or hydrochloric acids. Swallowed in any quantity, the strong acid is an intense corrosive poison. Burning pain in the mouth, throat, and stomach is experienced in the very act of swallowing, speedily followed by violent vomiting, the ejecta being intensely acid and containing blood. The voice is apt to become changed and whispering, and the shock from the corrosion is usually very severe, the sufferer very likely dying in collapse in from eighteen to twenty-four hours after taking the poison; or, in exceptional cases, even much earlier—in a few instances so early as two or three hours. If the poison be not speedily fatal, parotitis with salivation and nephritis are not uncommon sequelæ. The severity of the poisoning is largely influenced by the fact of presence or absence of food in the stomach, the former condition saving from direct contact of the concentrated acid upon the gastric walls. One drachm is about the least quantity reported to have produced death, and on the other hand, so large quantities as from two to three ounces have been swallowed and the patient has recovered. The lesions in sulphuric acid-poisoning are patches of corrosion where the acid has struck. Mouth, throat, and œsophagus may show whitish, or ashen, or brownish areas of corrosion, and in the stomach patches of brown, or black may alternate with lines of red, where the mucous membrane, protected by foldings from concentrated action of the acid, has escaped corrosion, but has taken on inflammation. Perforation of the stomach is common. The gastric contents are generally discolored a dark brown and are of viscid consistence, and may show no traces of the acid, especially if death have been postponed several days and the patient have been under treatment. In such cases all the acid will have been discharged in the early vomiting. The treatment of sulphuric acid poisoning is to neutralize the acid, and then treat the lesions on general medical principles. For neutralization, magnesia and chalk are commonly chosen; but, as Taylor points out, a soluble alkali like the sodic carbonates, given in solution, will obviously act more certainly and speedily. Whatever alkali be selected, it should be given freely, but, at best, neutralization accomplishes little, since the damage is done at the moment of swallowing the acid. Demulcents, such as milk, gruel, white of egg, and oil should, next, be freely administered. The stomach-pump should be avoided, lest the nozzle perforate the corroded gastric walls; and the spontaneous vomiting is so free that there is no indication for the giving of emetics.

The most important points of medical jurisprudence connected with the subject of sulphuric acid-poisoning are these: First, that fatal poisoning by this agent almost certainly means either suicide or accident. For the acid is so intensely sour that it is hardly conceivable that a fatal dose, criminally offered, would be unsuspectingly quaffed by the intended victim, even though attempted to be disguised in some article of food or drink. Forcible administration to children, or drunken or sleeping persons, is, however, possible, and a few cases of homicide of children by this method have been reported. Next, the jurist must remember that the acid may kill without actual swallowing, death ensuing by asphyxia from swelling of the larynx, corroded by the poison; and, next, that in any case the mouth and lips may show no marks of the acid if the draught have been taken from a *spoon*. In rare cases even throat and œsophagus have shown no signs of corrosion. Again, although the symptoms almost invariably begin immediately upon swallowing, even if the potion have been one of diluted acid, and the pain is intensest agony, yet the sufferer may at first be able to walk and even disguise his sufferings from the notice of casual observers. As regards period of death, the acid has killed in so short a time as one hour, and at all intermediate periods thereafter up to the lapse of two years. Rapid deaths are generally by suffocation, from occlusion of the larynx, and long delayed ones from stricture of the œsophagus.

Therapeutically, strong sulphuric acid is occasionally used as a caustic, but the very intensity of its action is in its disfavor, so that nitric acid is generally preferred. The acid must be kept in glass-stoppered bottles.

Diluted, so as not to be corrosive, sulphuric acid, like all sour acids, tends to check acid, and to increase alkaline secretions, to inhibit fermentations, and, of course, to neutralize alkalinity. Dilute preparations of sulphuric acid are, therefore, available to repress morbid sweatings, both applied locally as lotions, and given internally to allay thirst and quicken appetite; to prevent fermentation of food in the primæ viæ, and so to cure diarrhœas due to the irritation of the products of such fermentations, and to neutralize the alkali of alkaline pyrosis. For these various purposes the following officinal preparations of the United States Pharmacopœia are available:

Acidum Sulphuricum Dilutum, *Diluted Sulphuric Acid.*—This preparation is a simple aqueous dilution of sulphuric acid, of ten per cent. strength. It is a colorless

fluid, intensely sour of taste, and of about the specific gravity 1.067. It should be kept in glass-stoppered bottles. This grade of acid, although not corrosive, is quite irritant, and, for medical use, requires considerable further dilution. The dose is from ten to thirty drops, diluted thirty- or forty-fold, and to be taken through a tube, with the mouth well rinsed after the swallowing.

Acidum Sulphuricum Aromaticum, *Aromatic Sulphuric Acid, Elixir of Vitriol.*—This preparation consists of alcohol charged with sulphuric acid and tincture of ginger, and flavored, in addition, with a trace of oil of cinnamon. In 1,000 parts of product are represented 200 parts of sulphuric acid, 45 of tincture of ginger, and 1 of oil of cinnamon. The preparation is a limpid, yellow fluid of an aromatic, ethereal, and strongly sour taste, and of the specific gravity 0.955. As its odor suggests, it probably contains some ethereal product of a reaction between the acid and alcohol of its composition. The United States Pharmacopœia considers, thus, that there is a certain amount of ethyl-sulphuric acid present. Aromatic sulphuric acid should be kept in glass-stoppered bottles.

This preparation is the favorite one for the internal administration of sulphuric acid. It is to be given in the same manner as the dilute acid (see above), and in the same or somewhat lesser doses.

Edward Curtis.

SULPHUROUS ACID, H_2SO_3. Sulphur dioxide gas (SO_2) is readily absorbed by water, and in so dissolving is to be regarded as uniting with water, molecule for molecule, with the formation of the acid body, H_2SO_3. The United States Pharmacopœia recognizes under the officinal title *Acidum Sulphurosum*, Sulphurous Acid, an acid representing 3.5 per cent. of sulphur dioxide and 96.5 per cent. of water, and of the specific gravity 1.022 to 1.023. Sulphurous acid is a colorless fluid, smelling pungently of sulphur dioxide, and tasting both sulphurous and sour. It has a strong acid reaction, and first reddens and then bleaches litmus paper. It is wholly volatilized by heat, and tends constantly to undergo conversion into sulphuric acid by the absorption of oxygen. This change is hastened by the action of light, hence the Pharmacopœia directs that sulphurous acid be put up in glass-stoppered, dark amber-colored bottles, and be kept in a cool and dark place. The pharmacopœial process for making the acid is to generate sulphur dioxide by heating a mixture of sulphuric acid and charcoal, and to conduct the mixed sulphur and carbon dioxides into distilled water. The sulphur dioxide dissolves in the water with the formation of sulphurous acid, and the carbon dioxide mostly escapes.

In its medicinal properties sulphurous acid resembles sulphur dioxide (see Sulphur Dioxide), and may be practically regarded, indeed, as a simple aqueous solution of that compound. It is a pretty potent germicide, and upon tender surfaces of the animal body is decidedly irritant. It bleaches vegetable colors. The acid is used, externally, as a wash in parasitic skin diseases, generally diluted two- or three-fold, and, internally, is occasionally prescribed in cases of pyrosis and sarcinæ. It is, however, an exceedingly disagreeable medicine to take. The dose is 4.00 Gm. (about one fluidrachm) of the officinal acid, taken in a wineglassful of water.

Edward Curtis.

SULPHUR SPRINGS (TEXAS). *Location and Post-office,* Sulphur Springs, Hopkins County, Tex.

Access.—By the Jefferson Branch of the Missouri Pacific Railway.

Analysis.—Dr. J. M. Hooper, of Sulphur Springs, Hopkins County, Tex., sends us the following analyses of the water of two wells in that town. There is one well, he remarks, that has not yet been examined, which is thought, however, to be superior to these. He adds that he will be happy to answer any questions about the waters of the various wells in the town.

The water of the Weaver Well is acid in reaction, with a specific gravity of 1.008, and each gallon contains the following solid constituents:

	Grains
Sulphate of ferric oxide	33.421
Sulphate of aluminium	23.235
Sulphate of magnesium	24.345
Sulphate of lime	45.678
Sulphate of sodium	1.342
Sulphate of potassium	0.849
Chloride of sodium	1.560
Carbonate of lime	4.286
Phosphate of lime	0.633
Silicic acid	1.425
Free sulphuric acid	1.211
Nitrous acid	trace
Organic matter	2.473

The Pate Sour Well, also of acid reaction, has a specific gravity of 1.0096, and in each gallon the following solid constituents have been found:

	Grains.
Calcic sulphate	84.713
Ferric sulphate	63.194
Magnesic sulphate	22.991
Sodic chloride	5.017
Silex	1.944
Organic and volatile matter	3.797
Free sulphuric acid	1.321
Iodine	trace

G. B. F.

SUMACH (*Rhus Glabra*, U. S. Ph.). "The fruit of *Rhus glabra* Linn.; Order, *Anacardiaceæ*" (*Terebinthaceæ*). The smooth sumach is a very common, and, when in full fruit, a very striking, American shrub. It has, like all its genus, large pinnate leaves and small, polygamous, greenish, regular, pentamerous flowers in panicles; ovary single, one-ovuled; styles or stigmas three. This species has smooth, somewhat glaucous leaves, white beneath, of from eleven to thirty-one leaflets, and close, upright, terminal, conical panicles of flowers and fruit. Berries, when ripe, of a most brilliant crimson color; they are "sub-globular, about one-eighth of an inch (3 millimetres) in diameter, drupaceous, crimson, densely hairy, containing a roundish-oblong, smooth putamen. It is inodorous, and its taste acidulous." The pleasant acid taste of sumach berries is all in the crimson pubescence with which they are covered, and is due to malic acid and acid malate of lime; the internal parts of the seed contain, like the rest of the plant, tannic acid. A fluid extract (*Extractum Rhois Glabræ Fluidum*, U. S. Ph., strength $\frac{1}{10}$) is officinal. Either this diluted, or a decoction, may be used as a pleasantly sour, astringent gargle.

Allied Plants.—See Ivy, Poison.

Allied Drugs.—Tamarinds, Barberries, Rose Hips, etc.

W. P. Bolles.

SUMBUL, U. S. Ph. (*Sumbul Radix*, Br. Ph., Musk-root). The root of *Ferula Sumbul* Hook., f.; Order, *Umbelliferæ*. This large perennial herb, belonging to the asafœtida-, galbanum-, and ammoniacum-yielding group of the family, has a large, rather short, cylindrical root, attaining a diameter of four or five inches, and a length of say a foot, when it divides into several stout branches, and a tall, erect, rather simple stem, six or eight feet in height. The leaves are large, tripinnate, with broad, sheathing petioles. Flowers small, greenish, polygamous, in compound naked umbels. All parts of the plant, but especially the root, exude a resinous, fragrant, milky juice (Bently and Trimen, 131). The sumbul plant is a recent addition to medical botany, having been discovered by Fedschenko in Central Asia, in 1869. The root itself as a perfume, and afterward as a medicine, appeared in Europe about 1840.

Sumbul root comes in transverse slices, one or two or more inches in diameter, and from one-half to an inch in thickness; the surface of these dried disks is a dirty brown, or gray marbled with dirty white; the edges have a dark, loose, papery bark. Resin drops can be seen on it by aid of a lens. The tissue is hard, but spongy; odor decidedly like that of musk, but weaker.

Composition.—The most important constituent is the *resin*, of which there is nine per cent. (Flückiger); it has

a musky smell, more developed in contact with water, and a bitter, aromatic taste. The root contains also a small quantity of dull-bluish colored oil.

Action and Use.—Sumbul has not any important medicinal value; like asafœtida, and its namesake, musk, it is gently stimulant and slightly anti-spasmodic, and may be given for the same nervous conditions as they; but its principal employment is in the preparation of some perfumes, where it takes the place of musk. A tincture (*Tinctura Sumbul*, strength $\frac{1}{10}$) is officinal.

Allied Plants.—See Anise.

Allied Drugs.—Asafœtida, Musk, Valerian.

W. P. Bolles.

SUMMIT MINERAL SPRING. *Location and Post-office*, Harrison, Cumberland County, Me.

Access.—By the Grand Trunk Railway to Norway Station; thence by conveyance nine miles to the spring.

Analysis (46° F., F. L. Bartlett).—One pint contains:

	Grains.
Carbonate of soda and potassa	0.175
Carbonate of magnesia	0.031
Carbonate of lime	0.123
Chloride of sodium	0.021
Oxide of iron and alumina	traces
Silica	0.122
Organic and volatile matter	0.029
Total	0.501

Therapeutic Properties.—This is almost an absolutely pure water, and on that account alone it should be valuable as a solvent and general tonic. The State of Maine abounds in these pure springs, some of which have established reputations as therapeutic agents—for example, the Poland and the Underwood Spring.

G. B. F.

SUMMIT SODA SPRINGS. *Location*, Alpine County, Cal.

Access.—By Central Pacific Railroad to Soda Springs Station; thence by stage twelve miles to the springs.

Analysis.—One gallon contains:

	Grains.
Bicarbonate of lime	43.20
Carbonate of magnesia	4.20
Carbonate of soda	9.50
Chloride of sodium	26.22
Oxide of iron	1.75
Silica	2.06
Alumina	1.75
Potassa	trace
Total	88.68
	Cub. in.
Carbonic acid	186.35

Therapeutic Properties.—The presence of so large a proportion of carbonic-acid gas in this water, together with the oxide of iron, furnishes the latter in a very desirable form—that of the carbonate. There is no doubt but that this water will eventually prove very popular as a tonic and alterative agent.

These springs are situated in the Sierra Nevada Mountains of Eastern California, at an altitude of about seven thousand feet. Game abounds in the surrounding country. From the latest accounts no hotel had yet been erected at the springs.

G. B. F.

SUNDEW (*Drosera*, Codex Med.), *Drosera rotundifolia* Linn.; Order *Droseraceæ.*

This little plant, and others of its genus, have been used now and then for generations in medicine, generally for phthisis, and as often have fallen into neglect. They appear to contain, besides ordinary vegetable products, a peculiar acid, irritating to the skin. In common with other insectivorous plants, the glandular hairs of the leaves secrete a substance capable of dissolving albuminous substances. They have probably no medicinal value.

Allied Plants.—The most interesting plant in the order is the famous Venus Fly Trap, *Dionæa Muscipula*, of North Carolina, whose leaves close like the jaws of a steel trap upon unfortunate insects alighting on them.

W. P. Bolles.

SUPERFŒTATION. By this term we mean the impregnation of a female already pregnant. Superfœtation proper must be clearly distinguished from superimpregnation (superfecundation). Most writers admit the possibility of the latter: *i.e.*, that two ova belonging to the same period of ovulation can be fecundated during sexual intercourse practised by the same or different persons near the same period of time. This seems to be proved by that class of cases in which the same woman has given birth to twins bearing evident traces of being the offspring of fathers of different races.

Dr. Mosely tells of a negress who brought forth two children, one a negro and the other a mulatto. She said that a white man on the estate had had intercourse with her directly after her black husband had quitted her. Rev. Dr. Walsh narrates the case of a creole woman who had three children at a birth, of three different colors—white, brown, and black—with all the features of the respective classes. Fodéré, on the authority of Buffon, records the case of a woman who gave birth to twins, one being white and the other black. She confessed that immediately after her husband had left her she was forcibly raped by a negro. Dr. Nowlin reports the case of a negress who gave birth to twins, one a pure African, with all the typical features of that race, and the other a very bright mulatto, exhibiting evident characteristics of the Caucasian race. The mother was a pure black, with all the typical features of the African, as was also her husband. Upon inquiry, he ascertained from the mother that she had permitted intercourse with a white man the day succeeding the same act with her husband. Such cases seem to have been very common in slave-holding countries, and Beck gives nearly half a page to such references.

Scanzoni, who rejects even the idea of superfecundation, explains such cases on the ground that children sometimes resemble the father and sometimes the mother, both in features and complexion. In twin pregnancies one child may resemble the father and the other the mother; and it seems quite possible that all that is necessary for the production of a black child and a white one is cohabitation between a black man and a white woman, or, what is vastly more common, a white man and a black woman—one child resembling the father and the other the mother. Few, however, agree with Scanzoni in this view, and the possibility of superfecundation is pretty generally admitted, being based chiefly on what we know from comparative physiology.

On the other hand, the possibility of superfœtation has been vigorously opposed by many writers, and the evidence in its favor leaves much room for doubt. The idea implied is, that a woman who is already pregnant may, at a stage of pregnancy more or less advanced, again conceive, and carry at the same time the fruit of two conceptions between which there must be a considerable interval.

It is admitted by all that superfœtation may take place in extra-uterine pregnancy, and in cases of double uterus or bilocular uterus. An example of this is reported by Montgomery, in which, while the product of an extra-uterine pregnancy remained encysted within the abdomen, the woman bore three children. Dr. Steigervahl records a similar case, and Dr. Cliét, of Lyons, reports a very interesting one in which a woman died suddenly, and at the post-mortem examination there was found an extra-uterine fœtus of five months in the abdomen and a fœtus of three months in the uterus.

A careful analysis of the so-called cases of superfœtation shows conclusively that the phenomena in most of them can be explained by twin pregnancies. But, on the other hand, there are numerous examples advanced in support of this idea which cannot be explained by this hypothesis.

One of the arguments is based on the cases in which two living children have been born at different and widely separated periods. The following are the intervals in some of these cases: Four and a half months, Marianne Bigaud; five and a half months, Benoite Franquet; five months, a woman of Arles; seventeen

weeks, a case of Dimerbroeck; six weeks, a case of Lebas; four weeks, a case of Dr. Moebus; fifty two days, a case of Thielmann; forty-two days, cited by Fordyce Barker; one month, Giuseppe Generali (*vide* Ganahl, "Superfœtation," Paris, 1867). Supposing that two children be born at an interval of four months, and both be capable of being reared, we must acknowledge that superfœtation is probable, or admit that a five-months' child is capable of being reared, which is in the highest degree improbable.

Another argument is advanced by Dr. Bonnar, who gives a number of cases in which children born in wedlock succeeded each other with very unusual rapidity. The question of superfœtation is here looked upon from a different point, in reference more particularly to the period after parturition at which the female procreative organs are again capable of exercising their functions. He gives three cases in which there intervened between the two deliveries 182, 174, and 127 days respectively; and all the children were sufficiently developed to be reared and, without exception, to reach maturity. In the latter case, subtracting from the interval (127 days) which occurred between the two deliveries 14 days, which Dr. Bonnar assumes to be the earliest possible period at which a fresh impregnation can occur after delivery, we reduce the gestation to 113 days—that is, to less than four months. As both these children survived, the second child could not possibly have been the result of a fresh impregnation after the birth of the first; nor could the first child have been a twin prematurely delivered, for, if so, it must have reached only a little more than the fifth month, at which time its survival would have been impossible.

In regard to the objections based on the supposition that the decidua so completely fills up the uterine cavity that the passage of the spermatozoa is impossible, we may say that the decidua reflexa does not come into apposition with the decidua vera until about the eighth week of pregnancy, and, therefore, until that time there is a free space between the two membranes.

Lastly, respecting the cessation of ovulation during pregnancy, this no doubt is the rule, but there are, however, a sufficient number of well-authenticated cases of menstruation during pregnancy to prove that ovulation is not always absolutely in abeyance.

Therefore, the most reasonable conclusion seems to be that, although the vast majority of cases of so-called superfœtation can be explained by twin pregnancies, there is a small number of cases which cannot be explained upon this hypothesis, and this makes the existence of superfœtation seem probable. *Dillon Brown.*

SUSPENSION SPLINT, HODGEN'S. The value of extension in the treatment of fractures of the femur is universally conceded. The effort to obtain continuous extension with immobility has resulted in a multiplicity of methods of treatment, some of which are complicated and troublesome, others cruel and inefficient. The most simple and effective *continuous extension* is found, I think, in oblique suspension, as first advocated by Nathan R. Smith, when he introduced his anterior splint. Suspension, with the amount of traction determined by the obliquity of the suspending cord, is more easily applied and efficiently maintained in that modification of Smith's anterior splint devised and so successfully used by the late Dr. John T. Hodgen, of St. Louis, than by any other method. This splint, in the hands of an expert, secures nearly perfect immobilization, and extension so equable and effective as to give practically perfect results. The freedom of motion allowed to the patient does not interfere with immobilization of the fractured bone.

The illustration shows the splint in use, with leg suspended, as for the treatment of fractures of the thigh. The simplicity of the structure of the splint is evident, and the manner of the suspension of the leg is made plain. The leg is resting on muslin strips which pass under it. These are secured by pins at each end, after overlapping the arms D E and D′ E′ of the splint. Each strip supports its proportion of the weight of the leg. These strips extend from the heel to the gluteal fold. The adhesive strip H, softened by warmth or by turpentine, is applied to the leg, and secured in position by a roller which extends as high as the knee. This strip secures the leg in the splint, since it is fastened by the cord and block N to the foot of the splint at F.

The splint itself is composed of a single piece of No. 2 wire, bent as shown in Fig. 3746. The sliding hooks D, D′ and E, E′ are used for attaching the suspending cords to the splint. The use of the arch O is to maintain the proper width of the splint at its upper end, viz., 20 or 25 ctm. (eight or ten inches). This arch is loose, and is easily slipped over the ends of the wire which forms the splint before the latter is applied to the leg. The width of the splint at the foot is about 10 ctm. (four inches), and is determined by the bend in the wire which forms the body of the splint. The wire hooks E, E′ and D, D′ present at one end a free loop for the attachment of the supporting cord, while the other end is coiled somewhat snugly about the lateral bars of the splint (at D and E). The lateral bars, to which the muslin strips are attached, extend upward on each side of the leg, so that the two ends of the wire reach, the one to a point above the pubes, and the other, on the outside, nearly to the crest of the ilium. The bend in the splint at the knee permits slight flexion of the leg.

The distance from the foot of the splint to the bend of the knee is 56 ctm. (twenty-two inches), and from the angle to the upper free ends 50 ctm. (twenty inches). The suspending apparatus is composed of, first, the pulley A, which is fixed in a framework over the bed, or, preferably, in the ceiling; secondly, the sliding block B, and the cord B, A, C; thirdly, of the two cords D, C, E and D′, C, E′, of equal length, and with a loop at each end for attachment to the wire hooks at D, D′ and E, E′. These cords are passed through a loop in the cord at its end C. The suspension of the leg and splint is readily accomplished by sliding downward the block B on the cord B, A, C.

The splint, as stated above, is a modification of Nathan R. Smith's anterior splint, the lateral arms being substituted for the anterior wires, to which the leg in his splint was to be secured by a roller bandage. Here the leg is sustained by the muslin strips, any one of which can be readily and quickly changed so as to give increased or diminished support to any part of the leg, thus maintaining the proper outline of the bone during the rapid atrophy of the soft parts which ensues upon the enforced rest of the limb.

The extension is maintained through the adhesive strip H, which, extending from one tuberosity of the tibia to the other, across the board N at the sole of the foot, is fastened by a cord to the cross-bar at F, and thus securely holds the leg in the splint. Through this medium the extending force is transferred from the splint to the leg. The board at the sole of the foot should be as wide as the adhesive strip, and about 7 or 8 ctm. (three and one-half inches) long. It then protects the malleoli from the lateral pressure of the adhesive strips through which the extending force is applied.

The splint as shown in Fig. 3745 is cheap, and readily made by any blacksmith. The splint as represented in Fig. 3746 is more expensive, but can be adjusted to a leg of any size.

The lateral bars B and C are hollow square tubes, furnished with thumb-screws at their extremities, B, C. These tubes are of sufficient size to admit the terminal ends of the lateral bars, and by pushing in or pulling out the extremities of the lateral arms the length of the splint may be varied. Its width can also be changed by sliding the lateral arms into the hollow tube A, A, which is furnished with thumb-screws at A, A. The splint is fitted by sliding B, A and C, H to the proper point, and securing them by setting the thumb-screws at B and C. The hooks D, E, for suspending the splint, slide on the lateral bars B, C. The splint is used in the same manner as the one before described. The foot-piece P is to prevent passive extension of the foot. Its use is optional with the surgeon. Its chief utility is found in cases of compound fracture of the leg. The foot-piece here

shown is a thin board fastened to the heavy cross-wire, which is curved so that one end fits around the lateral arm of the splint, and the other is so bent as to maintain the foot-piece at its proper angle. Dr. J. Freund, of Champion, Mich., has devised a foot-piece which answers a good purpose. It is held in position by two transverse slips of wood fastened by thumb-screws, and has the inclination of the foot-piece determined by a third thumb-screw which is fixed in one of the transverse slips.

The application of the Hodgen suspension splint is simple and, in skilful hands, painless. Suppose the leg, with its fractured femur, is resting upon the bed. A roller bandage is applied to the foot and ankle, to prevent swelling, excoriation, or tenderness, from the pressure of the bandage or of the adhesive strips on the malleoli. Then

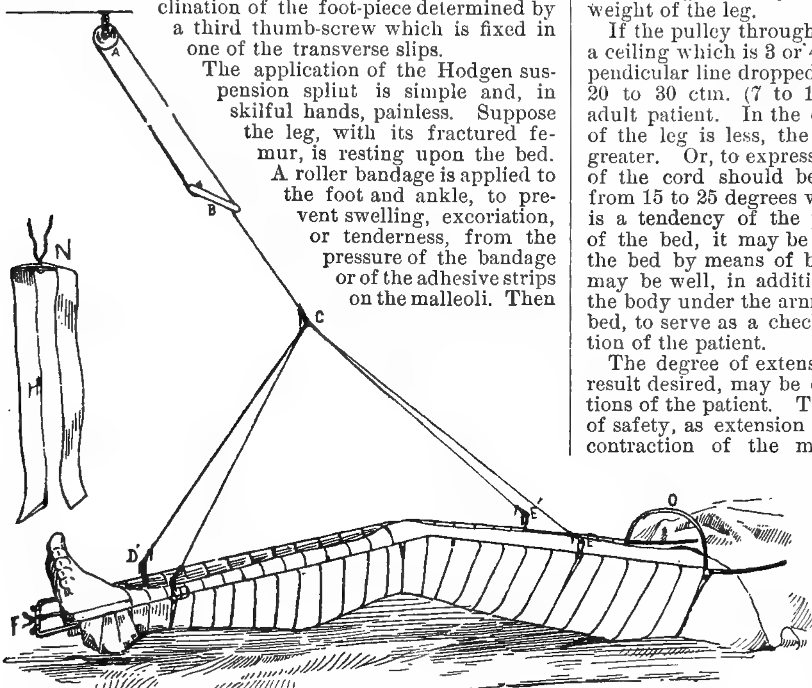

Fig. 3745.

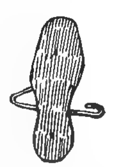
the adhesive strip H, with its foot-piece and cord, is placed in position, an assistant grasps the foot with one hand, and, with the other hand under the knee, lifts the leg from the bed, while at the same time he makes steady extension of the femur. The surgeon then continues the application of the roller as high as the knee-joint, and thus secures more perfect adhesion of the plaster to the leg. The leg is again allowed to rest upon the bed, but the assistant maintains moderate traction on the foot, so as not to relax extension of the fractured bone while the splint is put in position. A lateral arm of the splint is placed upon either side of the leg, and the cross-bar is brought close to the sole of the foot. The cord and block N, with the adhesive strip, is now fastened to the foot of the splint. Strips of muslin are passed under the leg, one at the ankle, one at the knee, and perhaps two under the thigh. These are secured by pins to the lateral arms of the splint, while it is held with its upper end so that the inner arm is above the pubes, and its lower end is on a level with the malleoli. The leg can now be suspended by attaching the cords D E and D' E', and adjusting the slide B so as to lift the splint and leg from the bed. The cradle of cloth strips upon which the leg is to rest, is now made complete by adding strips of muslin, and adjusting them to the outline of the leg as indicated in the cut. The upper end of the wire which is to be above the pubes, may be bent upward to permit greater freedom in the movements of the body. No special or violent attempt at adjustment is made, nor is it necessary, except where there is marked lateral displacement, as in some transverse fractures. The free swinging of the leg, and the efficiency of the extending force, secure a perfect adjustment in a few hours. The fracture sets itself. The degree of extension is regulated by the obliquity of the cord and the weight of the leg.



If the pulley through which the cord passes is fixed in a ceiling which is 3 or 4 metres (9 to 12 feet) high, a perpendicular line dropped from the pulley should fall from 20 to 30 ctm. (7 to 10 inches) beyond the foot of the adult patient. In the case of a child, where the weight of the leg is less, the obliquity of the cord should be greater. Or, to express it more accurately, the obliquity of the cord should be sufficient to make an angle of from 15 to 25 degrees with the perpendicular. If there is a tendency of the patient to slide toward the foot of the bed, it may be obviated by raising the foot of the bed by means of blocks. In the case of a child it may be well, in addition, to pass a cord loosely about the body under the arms, and fasten it to the head of the bed, to serve as a check to any great change in the position of the patient.

The degree of extension necessary to accomplish the result desired, may be determined in part by the sensations of the patient. The position of comfort is the one of safety, as extension is required only to overcome the contraction of the muscles. The counter-extending force is the weight of the body. Much less extension is required in such splints as suspend the leg and remove the resistance of friction of the leg on the bed, than is required when the leg rests upon the bed, and weight and friction are first to be overcome. It is never necessary, when using this splint, to apply, in the case of an adult (as recommended by Hamilton when speaking of other methods of making extension), twenty pounds as an extending weight; or, as he states it in his work on "Fractures and Dislocations," published in 1880, "one pound for a child one year of age, two pounds for a child two years of age, and so on, adding one pound for each year up to the twentieth." An extension of twenty pounds, applied through an adhesive strip to the leg, and pulling upon the knee-joint and femur, is a serious trial to the patient's endurance, and it taxes the surgeon's ingenuity to maintain steadily such a force.

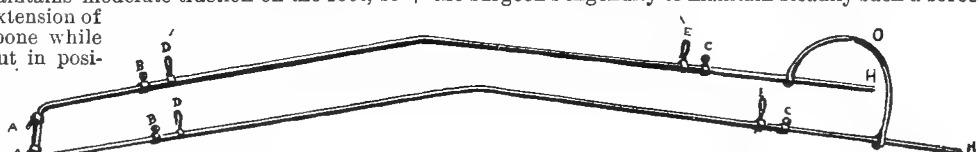


Fig. 3746.

The amount of extension required in this suspension splint is much less, being from three to ten pounds. This is all sufficient, for there is no friction to overcome, and so long as the patient maintains a position in bed approximating the one he occupied when the splint was adjusted, there is no variation in the extending force. It is quiet, persistent, non-irritating, and effective. There is no perineal band to fret and worry the patient. The extending force is determined by two factors, and these are entirely within control of the surgeon, viz., the obliquity of the extending cord, and the weight suspended. The first can be varied by the relative position of the bed and the suspending pulley, and the latter can be increased if desired by placing sand bags across the lateral bars of the splint. The weight of the leg distributes some of the extending force to each of the muslin strips

upon which it rests, and thus diminishes somewhat the traction upon the adhesive strip.

It seems difficult for some persons to understand how extension can be applied to a fractured thigh by direct traction upon the leg, without counter-extension through a perineal band. They fail to recognize the efficiency of the weight of the leg and the stability of the body, as a counter-extending force. The amount of the extending force that is transmitted through the adhesive strip in the suspension splint, may be measured by substituting a spring balance for the cord, which in the cut connects the block N with the foot of the splint. A small portion of the extending force is, however, transmitted through the strips which support the limb in its cradle, and those who wish can, by mathematical formulæ, compute the extending force.

Professor Francis E. Nipher, of the Washington University, and Dr. A. K. Worthington, used the following formulæ for determining the extending force (the line D in the diagram (Fig. 3747), represents, approximately, the line of the splint and of the femur):

The pull on the short cords, C E, and C E', and also that on C D, and C D' (see Fig. 3745), can be accurately measured. The angles *a* and *b* (Fig. 3747) can also be measured. The traction force along C E, and C E', is represented by *A*, and that along C D, and C D', by *B*.

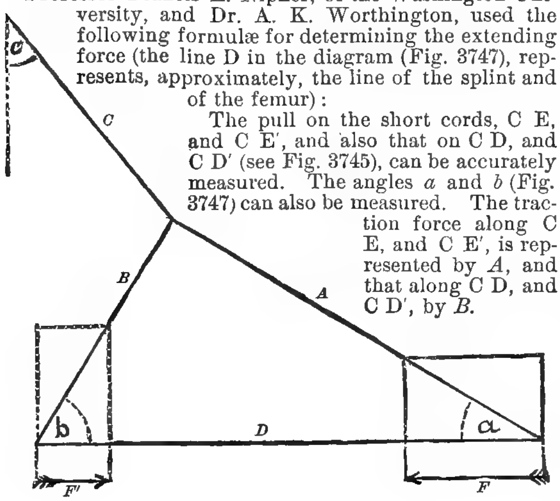

FIG. 3747.

The forces *A* and *B* being known, as also the angles *a* and *b*, we can readily calculate the horizontal components, F and F'. The resultant of F and F' will represent the direct traction force exerted along the line D; or the amount of efficient extension applied in the line of the femur.

In a particular case, where the patient weighed 150 pounds, and the suspending cord, C (or in Fig. 3747, A, B, C) formed an angle of 15° with the perpendicular:

It was found that the pull...........	A = 11.5 pounds.
and the pull.........................	B = 10.5 "
The angle............................	a = 40°.
The angle............................	b = 75°.
Hence, by trigonometry...............	F = A cos. a,
and..................................	F' = B cos. b.
Whence by substitution...............	F = 11.5 x cos. 40 = 8.8 pounds.
" "	F' = 10.5 x cos. 75 = 2.7 "
Therefore the resultant of	F and F' = 6.1 pounds.

F and F' act in different, opposing directions, hence their resultant is the difference between them, or 6.1 pounds, which represents the amount of the extending force applied to the femur in this case. If the angle C was increased to 36°, it was found:

That the angle	a = 35.
" "	b = 105,

and the force or pull on

A = 14 pounds.
B = 12.5 "

Here the forces F and F' are exerted in the same direction, since the angle *b* is greater than a right angle, and their resultant is the sum of the forces which (by the same formulæ as before) is found to be 14.7 pounds. The weight of the leg was estimated at 21 pounds.

The loop C, in the cord B, A, C (Fig. 3745), is loose and can be slipped along the cords D, C, E, and D', C, E', and the angle made by these cords with the splint should be changed with the obliquity of the suspending cord, B, A, C.

The leg is open for inspection, and the supporting strips can be readjusted as the parts atrophy. The slight natural anterior curve of the femur can be maintained. The circulation is undisturbed, the nutrition is not interfered with by the pressure of the retentive apparatus, and is as perfect as it can be during the enforced quiet. The leg can be kept cool or warm, as desired. The patient may sit up or lie down, as comfort suggests. The bed-pan can be used without disturbing the fracture, and the best possible result can be obtained, viz., no shortening and early union, without bed-sores or any of the constitutional complications which are liable to follow confinement in a fixed position.

The flexion of the knee is sufficient only to put the leg in a comfortable position, relaxing slightly the tension of the hamstring muscles and the gastrocnemius. The slight flexion of the thigh on the pelvis puts at rest the psoas and iliacus, and the rectus extensor of the thigh. The muscles are placed in a state of equilibrium.

The splint is well adapted to the treatment of all fractures of the femur, whether they are intra- or extra-capsular, through the trochanters, the shaft, or the condyles. Nor does the age of the patient interfere with its use, though a fixed dressing may be more convenient for children under six months or a year of age.

After a long and successful experience with the splint in private practice and hospital work, and after having observed its employment by the late Dr. John T. Hodgen during the last fifteen years of his life, I know of but one practical difficulty which arises in its universal and immediate use in all fractures of the femur. This objection pertains only occasionally to the fractures of the middle third of the bone in children. These exceptions are rare, extremely so, and if a perfect adjustment of the extending force to the necessity of the individual case could be obtained at once, they would be reduced to a minimum. The objection is found in the spasmodic contraction of the muscles, which at times is so frequent and violent, immediately after injury, that some lateral pressure is necessary to the comfort of the patient. This spasm may in part be controlled by lateral supports to the thigh, or by permitting the leg to rest upon the bed with extension applied after Buck's method. No form of dressing will uniformly control it. After this irritability subsides, the leg is more comfortably and more efficiently treated in the suspension splint. This clonic contraction of the muscles is more likely to be present if the extending force is in excess of the necessities of the case. The excessive tension acts as an irritant to the muscles.

Fortunately these cases are rare. Clonic contractions will, in isolated cases, occur in any splint and under any plan of treatment, for no lateral support or compression can prevent the contraction which accompanies a muscular spasm.

Opiates are sometimes useful, in the case of nervous children, for a few days after such an injury is received. The splint, and the manner of applying extension, afford the most perfect means of neutralizing the tonic contractility of the muscles, which so often determines shortening. The oblique suspension gives continuous and equable extension of an amount sufficient to accomplish a perfect result, without waste of any force, and it insures to the patient the most perfect liberty attainable by any known means compatible with comfort and safety.

H. H. Mudd.

SWEET CHALYBEATE SPRINGS. *Location and Post-office,* Sweet Chalybeate Springs, Alleghany County, Va.

ACCESS.—By the Chesapeake & Ohio Railway to Alleghany Station; thence by stage about ten miles to the springs.

THERAPEUTIC PROPERTIES.—This is a famed and valuable calcic-chalybeate water, used either as a beverage or for bathing. There are four springs, differing little in

composition. The water is sparkling, and has a sweet and ferruginous taste. It is indicated in all conditions accompanied by anæmia, chlorosis, etc.

These springs are located in the western part of Virginia, in a valley of the Alleghany Mountains, amid the beautiful scenery of that section. There are good hotel accommodations and bathing conveniences of all kinds. The flow is eight hundred gallons per minute.

ANALYSIS.—

	Grains.
Carbonate of lime	0.337
Chloride of sodium	0.011
Chloride of magnesium	0.196
Chloride of calcium	0.003
Sulphate of soda	0.404
Sulphate of magnesia	0.897
Sulphate of lime	4.110
Sesquioxide of iron	0.092
Total	6.050

Carbonic-acid gas, 13 cu. in. Temperature, 75° F.

Average temperature at hotel:

	6 A.M.	12 M.	6 P.M.
July 2 to September 5, 1870	70⅜°	84⅜°	78°
July 24 to August 19, 1871	65°	80°	78°

Organic matter	4.01300	3.04696
Total	152.27140	1,052.94695

THERAPEUTIC PROPERTIES.—The Sweet Spring is a mild and agreeable saline water, of efficacy in digestive and urinary disorders. The Akesion is a very strong saline, impregnated with sulphur, and is much employed as an active cathartic.

The extensive and commodious baths add greatly to the comfort and remedial value of this resort.

These springs are located in Western Missouri, on the bank of the Blackwater River. The hotel, a large building with modern appliances for convenience and comfort, stands in a well-shaded lawn of thirty acres, and, with the numerous cottages, affords the best of accommodations. The arrangements are most complete for all descriptions of baths, including two plunges, each thirty-four feet in diameter. The baths are supplied from the salt-sulphur springs, five miles distant, the water being pumped at the rate of two hundred thousand gallons per day. In addition to the above two springs there are two others, the White and the Black Sulphur, the waters of which are supplied when desired.

G. B. F.

SWEET SPRINGS (W. VA.). *Location and Post-office,* Sweet Springs, Monroe County, W. Va.

ACCESS.—By the Chesapeake & Ohio Railroad to Alleghany Station; thence by stage ten miles to the springs.

ANALYSIS.—One pint contains:

	Grains.
Carbonate of magnesia	0.103
Carbonate of lime	3.757
Chloride of sodium	0.017
Chloride of magnesium	0.039
Chloride of calcium	0.018
Sulphate of soda	0.793
Sulphate of magnesia	1.174
Sulphate of lime	1.646
Peroxide of iron	0.018
Iodine	trace
Earthy phosphates	trace
Silica	0.021
Total	7.586
	Cub. in.
Carbonic-acid gas	11

THERAPEUTIC PROPERTIES.—These are well-known and valuable calcic waters. Their natural temperature is about 75° F., which renders them very popular as baths. The contained carbonic-acid gas and the slightly sweetish taste (common to calcic waters) induce one to drink of the waters freely, and thus diuresis and mild catharsis is promoted. We are of the belief that their value in gravel, dyspepsia, and sterility is due chiefly to the quantity which one is able to take, thereby establishing a physiological condition of the secretive organs, rather than to any contained ingredients.

These springs are located in a beautiful valley, between the Alleghany and Sweet Springs Mountains, at an elevation of two thousand feet above the sea. The surrounding country is charming, and affords numerous delightful drives and walks to many points of interest. The hotel and cottages, built of brick, afford first-class accommodations for eight hundred guests.

The bath-house is arranged to supply hot and cold baths, of either mineral or pure water, and contains two large plunges, about sixty by thirty feet. The flow of the springs is eight hundred gallons per minute.

G. B. F.

SYCOSIS, sometimes called sycosis non-parasitica, to distinguish it from tinea sycosis, is a chronic inflammatory, non-contagious disease of the skin, involving the hair-follicles, characterized by the formation of pustules, papules, and tubercles, which are perforated by hairs. The subjective sensations are burning and itching. The disease is confined to the beard and hairy parts of the face. Papules and then pustules form, each one having a hair as its centre, and showing little inclination to rupture. The pustules are generally discrete, but are sometimes so numerous as to be crowded together. They are accompanied by marked redness of the surrounding skin, sometimes by swelling, burning, and pain. Unless the suppuration is profuse, the hairs cannot be extracted without giving much pain. The cause of the disease is not known. It sometimes, however, occurs on the upper lip, following nasal catarrh. It occurs equally in those who shave and in those who do not. The disease is essentially an inflammation of the hair-follicles. In the early stages the hairs are firm in their follicles, but when there has been a good deal of suppuration they become loose and may be pulled out. A cicatrix, with baldness, is then apt to result.

Sycosis is apt to be mistaken for eczema of the beard, and more especially for tinea sycosis, or true barber's itch. From the latter it is, however, distinguished by several marked characteristics. In both affections the hair-follicles are attacked; but in the parasitic disease the lesions are simply large, rounded red lumps, or nodules of various sizes, with few or no pustules. The hairs, however, in spite of the fact that there is no suppuration about their roots, come away easily, and sometimes drop out spontaneously. The discovery of the spores of the vegetable parasite in the roots of the diseased hairs, when looked for under the microscope, will greatly aid in the diagnosis. (See under Tinea.) From eczema of the beard, sycosis is distinguished by the absence of oozing or itching, and also by the fact that eczema rarely attacks the beard without showing itself elsewhere. It spreads about in crusts and pustules in the neighborhood, while sycosis is

strictly marked by discrete pustules, each with its hair running through the centre.

External treatment is that most generally useful in sycosis. Exposure to irritating influences is to be avoided. The hair should be kept clipped close or shaved. The latter is to be preferred. Although painful at first, it is in some cases absolutely necessary, if a favorable result is to be reached, that shaving should be practised every second or third day, according to the rapidity with which the beard grows. When shaving is to be performed for the first time, the hairs should be clipped close, and then a poultice should be applied to soften the crusts. After such careful preparation, the use of the razor is much less painful than it would otherwise have been. Shaving having been established as a habit, the local medical treatment may be begun. When the disease is acute, and there is a good deal of pain and swelling, black wash may be thoroughly applied every two or three hours, followed each time, so soon as the skin is dry, by oxide of zinc ointment, gently applied by means of the finger, or spread upon soft linen and bound upon the parts.

The following wash, not to be followed by ointment, is likewise of service in acute sycosis: ℞. Pulv. zinci carb. precip., pulv. zinc. ox., āā 4 Gm. (ʒ j.); glycerinæ, 8 Gm. (ʒ ij.); liq. plumbi subacetat. dil., 8 Gm. (ʒ ij.); aquæ rosæ, 240 Gm. (℥ vijss.). M.

In subacute cases the following wash is very good: ℞. Sulphur. precipitat., 8 Gm. (ʒ ij.); pulv. camphoræ, 0.65 Gm. (gr. x.); pulv. tragacanth, 1.3 Gm. (℈ j.); aquæ calcis, 128 Gm. (℥ iv.). M. Shake well, and apply from two to four times a day. If ointments are to be employed, the following will be found soothing in the acute stage: ℞. Pulv. zinc. carb. precip., pulv. zinci ox., āā 4 Gm. (ʒ j.); ung. aq. rosæ, 32 Gm. (℥ j.). M. To be applied immediately after shaving. Another convenient ointment, slightly more stimulating, is composed of 1 part of calomel to 32 parts of oxide of zinc ointment.

When the affection is of long standing, and when there is much infiltration, sapo viridis should be well rubbed in with a flannel rag and a little water, then washed off, and finally diachylon ointment should be applied. Depilation is to be used only when the roots of the hairs are loosened by suppuration.

The prognosis in sycosis should be guarded, for while some cases yield readily to treatment, others, particularly when the disease involves a considerable area of the face, last for months and even years. In spite of the most assiduous attention, relapses are not uncommon.

Arthur Van Harlingen.

SYMPATHETIC NERVOUS SYSTEM, DISORDERS OF THE. Under this heading it is mainly intended to discuss the grounds for and against the commonly accepted opinions as to the origin of certain troubles being due to disorders (functional or organic) of the sympathetic system of nerves.

Although the physiology of the sympathetic has been advanced considerably within recent years, there has not been a commensurate advance in our knowledge of its diseases.

In fact, with the exception of a few important symptoms which we know to have a direct causal connection with alterations in the sympathetic, our knowledge of its diseases is very superficial and in many cases purely problematical.

Of the many diseases that are attributed to changes or alterations in the sympathetic, the following are the chief: Hemicrania, exophthalmic goitre, angina pectoris, Addison's disease, diabetes mellitus, unilateral hyperidrosis, glaucoma, neuro-retinitis, ophthalmia neuro-paralytica, etc.

Hemicrania or Migraine.—In 1860 Du Bois-Reymond noticed, while suffering from an attack of migraine, that the temporal artery on the affected side was hard and cord-like to the touch, that the face on the same side was pale, and the eye retracted and injected.

During the decline of the attack the ear on the affected side became warm and red. He concluded that the cause of the attack was a tetanic contraction of the coats of the vessels on the affected side of the head.

It is impossible to account for this spastic contraction on any other grounds than that there is an affection of the sympathetic or of its medullary centre. Du Bois-Reymond looked upon this spastic contraction as the fundamental cause of the terrible pain present in these cases. He compares the pain to that of uterine pain in labor, and considers that it is due to pressure on the nerves of sensation in the muscular tissue.

The above views so ably put forward by their distinguished originator are, however, entirely inadequate to a proper explanation of the origin and course of a true migrainous attack.

I think it must be admitted that true migraine is an essential neurosis—that it is, in fact, due to a discharge from the sensory area of the brain, "or in that part of the sensory area which is the anatomical correlative of the sensation of pain in the head." [1]

The discharge is seldom, however, entirely limited to the sensory area of the brain, but is found to extend to other parts. Frequently it extends to the medulla, especially to the vaso-motor centre. It is in this way that the vaso-motor phenomena are more truly explained. The discharge may involve the cilio-spinal region and in this way cause the oculo-pupillary phenomena occasionally seen during an attack.

It will be seen, therefore, that the phenomena of sympathetic disorder present in migraine are only a result, and that only occasionally, of deeper-seated change. It is, therefore, according to this view, incorrect to speak of migraine being a disorder of the sympathetic system. Further, it is only on this view that a satisfactory explanation can be given of migraine.

Exophthalmic Goitre.—In spite of the able and persistent attempts made to explain the phenomena of exophthalmic goitre by attributing them to changes in the sympathetic, we are at the present time further away than ever from accepting such an explanation. At first sight it appears to be comparatively easy to explain wholly and completely the remarkable triad of symptoms by referring them to lesions of the sympathetic system, but, on deeper examination of many reported cases, it will be at once apparent that this cannot be the true explanation of this affection.

Very numerous opinions have been advanced at different times as to the nature of this disease, at first attributed to deficiency of the cellular elements of the blood, and afterward to organic lesions of the heart.

Laycock was the first to include the disease among the pure neuroses. Trousseau was the first to maintain its sympathetic origin.

To discuss this subject fully, it will be necessary to deal with the symptoms individually.

We will first treat of the cardiac palpitation, which is an essential symptom. It is always present. The other symptoms may be each and *all* absent, and still we may have to do with exophthalmic goitre. They may all be present, but unless there is a greatly increased cardiac action accompanying them, then we have not to do with exophthalmic goitre. To account for this increased cardiac action, irritation of the accelerator fibres running in the sympathetic has been assumed, and to explain the dilated condition of the thyroid vessels, a paresis of the vaso-motor fibres running in the sympathetic had to be supposed. We are asked to believe that one and the same change brings about two distinctly opposite effects; viz., paralysis of one set of fibres (vaso-motor) and irritation of another set (accelerator). This is certainly highly improbable, but what is contrary to all sound physiological principles is, that any one set of fibres can remain in a constant state of irritation for many months or even for many years.

Friedreich interprets the palpitation as being due to a paralysis of those vaso-motor fibres which supply the coronary arteries, and in this way leading to more blood being sent to the muscular tissue, and consequently to increased vigor of its ganglia. The unstable heart of the exophthalmic patients points to poverty of blood-supply

rather than to an excess. We therefore see, no matter on what grounds the sympathetic origin of the circulatory derangements present in this disease is attempted to be explained, that they are entirely inadequate.

If, then, the essential symptom of the disease be unexplainable by supposing a sympathetic lesion, it is unlikely, indeed, that the disease can be brought about by such a lesion.

The exophthalmos is no doubt due to various causes, increased fat in the cellular tissue of the orbit being one of these. This has been proved in a number of instances at the post-mortem examination.

Those who contend for the purely sympathetic origin of this disease consider that the exophthalmos is principally caused by contraction of the muscles of Mueller, induced by irritation of the cervical sympathetic.

As a proof of the very unsettled state of our knowledge of the nature of this affection, it is enough to say that other writers have attributed the loss of consentaneous movement between the globe of the eye and its lid to paresis of Mueller's fibres.

If exophthalmic goitre were really an affection of the sympathetic, we would expect to find changes in this nerve in fatal cases. Although, in a few of the recorded cases, changes have been found, *post mortem*, in the cervical sympathetic and its ganglia, there has been no constant relation between the severity of the symptoms present during life and the extent of the changes after death. Even coarse lesions of this nerve and its ganglia have been found in cases where, during life, there has been no suspicion of any exophthalmic goitre. Again, in well-marked cases of the disease, no changes have been found by such competent observers as Recklinghausen, Wilks, Paul, Ranvier, and Ross.

One strong reason for thinking that the essential cause of the affection is elsewhere than in the sympathetic is the absence of any pupillary changes. It is hardly possible to conceive of great changes in the trunk of the sympathetic without changes in the size of the pupil.

There are facts of a positive character which point strongly to the central nervous system as being the seat, at least, of the principal and initial changes.

Filehne has produced protrusion of the eyeballs, enlargement of the thyroid gland, and increased action of the heart in rabbits by wounding the restiform bodies.

The rather frequent occurrence of glycosuria, and even diabetes, points also in the direction of the central origin of the trouble. So also do tremor and the extreme restlessness and sleeplessness which are frequent symptoms. Insanity in various degrees is also corroborative of this view, and, lastly, may be mentioned cases of this disease complicated by ophthalmoplegia externa. There is, for instance, the well-known case of Warner and Bristowe, where, in addition to ophthalmoplegia externa, there was bilateral paresis of the seventh and fifth nerves, and tremor of the legs. Another strong clinical argument for the central origin of this disease is that, at times, it has been seen complicating progressive muscular atrophy—accompanying this disease as does bulbar paralysis.

The evidence adduced is, I believe, sufficient to prove that the cause of exophthalmic goitre is due to certain changes in the medulla. These changes principally affect the vaso-motor centre. What their precise nature may be is unknown.

Jendrassik [2] maintains that they are of an inflammatory nature. He considers that exophthalmic goitre is due to a polio-myelencephalitis.

Unilateral Progressive Atrophy of the Face.—There are several cases on record where undoubtedly this disease was directly due to some injury of the sympathetic in the neck. The vaso-motor and trophic fibres of the face run in the sympathetic before passing to the trigeminus. In addition to the face-atrophy in the cases above referred to, there were present symptoms indicating injury of the oculo-pupillary branches of the sympathetic also. The majority of these cases are, however, due to disease of the nucleus of the fifth, or to direct injury of the nerve itself after it has received the vaso-motor and trophic fibres for the face.

Angina Pectoris.—In the present state of our knowledge of the nature of angina pectoris it is impossible to say to what extent the sympathetic is involved. There are, no doubt, many instances of this disease where the symptoms present are, at any rate partly, due to disturbances of the sympathetic, but whether this disturbance is primary or secondary we are unable to say. It is common to describe an "angina pectoris vaso-motoria;" that is, an angina due to irritation of the vaso-motor nerves. This irritation leads to contraction of the arterioles, and consequently greatly increases the work of the ventricles. The resistance to the passage of blood may be so great as to bring about acute cardiac starvation, and consequently lead to an attack of true angina.

Probably, however, the strongest evidence that we have of the reality of a true vaso-motor angina is the result obtained by the action of drugs. It is an every-day observation that the nitrites, which quickly dilate the arterioles, rapidly relieve an attack, or prevent it from coming on.

We, however, are entirely ignorant of the way in which this special vaso-motor irritation is brought about.

Addison's Disease.—In a number of cases of Addison's disease there have been found extensive pathological changes in the abdominal plexuses of the sympathetic as well as in the suprarenal capsules. On the other hand, we have quite a number of post-mortem records of this disease where the sympathetic was perfectly normal. This represents our present knowledge of this subject; and it is too scanty to lead to any definite conclusion. Even if we had positive information as to the primary origin of the changes in the sympathetic, we would be unable to explain the connection between them and the symptoms of the disease.

Unilateral Hyperidrosis.—This may occur alone or as one of a group of symptoms. As the latter it is occasionally seen in exophthalmic goitre, diabetes mellitus, tabes dorsalis, and in general paralysis of the insane. It may be limited to the neck and face, or it may involve the whole of one side of the body. It is highly probable that this symptom is owing to a lesion of the sympathetic itself or of its medullary or spinal centres.

Diabetes Mellitus.—Notwithstanding the length of time that the clinical features of this disease have been known, we have as yet no adequate explanation of its true nature. Many and varied have been the offered explanations. An explanation which at times has received much support is the one attributing the fundamental cause to changes in the sympathetic. It is well known that we can induce diabetes experimentally by irritating what is called the "diabetic area" in the floor of the fourth ventricle. This area corresponds with the chief vaso-motor centre. Sugar may also be made to appear in the urine by irritating the sympathetic in the neck, or in any part of its course above the tenth rib. In these situations the sympathetic contains the vaso-motor fibres for the vessels of the liver.

Such experimentally induced glycosuria gradually disappears entirely, even when the cause that induced it is still in operation. That occasionally a temporary glycosuria may be induced in man by irritation of the sympathetic, where it contains the vaso-motor fibres of the liver, is highly probable. It is, however, as highly improbable that a true (essential) diabetes can be due to any such changes.

James Stewart.

SYMPATHETIC OPHTHALMITIS is an inflammation of one eye caused by a pre-existing inflammation in the other. It is therefore a secondary process in a previously healthy organ, induced wholly by a diseased condition in the corresponding but distant organ.

In the vast majority of cases the primary cause is a traumatism inflicted upon the first eye, which is followed by an inflammation usually somewhat prolonged. After a period varying from a few days to years, this is followed by an inflammation in the other eye, and it is to this that the designation sympathetic is given.

The first definite or accurate description of the disease was given in 1844,* by Dr. Wm. Mackenzie, the Glasgow ophthalmologist, who, adopting the pathological views reigning at that time, called it reflex or sympathetic ophthalmia, thus distinctly claiming for it a nervous character. This view has been almost universally held until within a couple of years past, when the bacteriological investigators have invaded this, as they have gradually almost every other, field in pathology, and there are now quite pronounced differences of opinion concerning the nature of the affection.

Whatever views may finally be accepted as to the pathogenesis of the disease, the clinical picture, as originally drawn, must be regarded as a remarkable instance of the result of keen observation and accurate deduction on the part of the great Scotch surgeon; and although since his time, as a result of the study of additional cases, our knowledge has increased, and we now know more of the complications which may arise and of the individual differences which may present themselves, still the important fact remains established, that a pronounced and usually fatal inflammation may arise in one eye as the direct consequence of an inflammation of its fellow.

The recent report of a collective investigation committee, appointed by the Ophthalmological Society of the United Kingdom, has added much to our practical knowledge of the subject; 211 cases (of which 131 were until then unpublished) were reported upon with various degrees of fulness, and I shall refer to that report with great freedom as the principal source of information in the compilation of this article; and the statistics there presented may be taken as representing about the proportions usually met with.

As has been stated, a direct traumatism is in the vast majority of cases the cause of the primary inflammation, and in 179 of the above cases this was distinctly the case. It was early noticed by Mackenzie that penetrating wounds in the ciliary region, involving in the cicatrix the iris, ciliary processes, or ciliary muscle, were especially liable to excite sympathetic ophthalmitis, and this report shows that in 100 cases it was distinctly mentioned, and in a certain proportion of 74 others this must have been the case, though for want of definite statements the exact number cannot be determined. In 21 others, an old perforating ulcer (presumably non-traumatic in origin) with phthisis bulbi was ascribed as the cause; in one a foreign body lodged for a long time undiscovered in the orbit; and in one there was irritation from an artificial eye occurring fifteen years after the enucleation of the globe. Several cases are reported in which the sympathetic ophthalmitis did not appear until after the enucleation of the eye first injured, and the question is thus presented whether it may not have been caused by the operation of enucleation, undertaken really as a therapeutic measure. In but seven cases was a spontaneous non-perforating inflammatory process stated directly to be the cause of the sympathetic disease, and these were all diagnosticated as spontaneous chronic irido-choroiditis. I have included among the traumatic cases six cases of glaucoma with iridectomy, in five of which the lesion in the fellow-eye presented the character of sympathetic ophthalmitis, not glaucoma—which, however, it has been asserted may by itself be truly sympathetic.

This report does not give a separate table of cases having foreign bodies remaining in the eye as a cause of the sympathetic disease, nor do the histories allow me to make one; it is to be inferred, however, in a large number; and the experience of ophthalmologists has always been that this is an especially dangerous condition, and more dangerous as the foreign body lies upon or approaches the ciliary region. This is *par excellence* the dangerous locality.

* Hirshberg has called attention to the fact that v. Ammon in 1835, in an essay on iritis, calls direct attention to a sympathetic iritis following a traumatic iritis of the other eye, and reports two cases, closing as follows: "The intimate sympathy of both eyes when disease is thus fully proved, making it the duty of the oculist, in cases of traumatic iritis of one eye, to pay the closest attention to the iris of the other, in order to detect at the outset sympathetic inflammation, by which the eye is liable to be lost." V. Ammon's essay is in Latin, I follow Hirshberg's translation.

Penetrating wounds in which the iris becomes included in the cicatrix, even when made intentionally by the surgeon, as in the operation for iridodesis, have so frequently had this unfortunate result, that the operation has, in a great measure, been abandoned as unjustifiable. Other operations in which a hernia of the iris is accidentally formed, as cataract extractions and even lacerations of false pupillary membranes following cataract extractions, by dragging upon the ciliary muscle and processes, have set up sympathetic trouble.

The form in which the sympathetic affection first shows itself is nearly always an inflammation of the uveal tract; it may be a simple plastic or a serous iritis, an irido-cyclitis, an irido-keratitis, or an irido-choroiditis. Exceptionally cases are reported in which the first distinct lesion is a neuritis, a neuro-retinitis, or a simple retinitis. Mackenzie, writing in pre-ophthalmoscopic times, and judging from the symptoms alone, believed the sympathetic lesion to be a retinitis, followed rapidly or accompanied by an iritis; but we now know that this is the exception, that the retina is not the part first affected, and that also, in a certain limited number of instances in which the disease runs a mild course, it escapes altogether. In later days it has been asserted that a true sympathetic glaucoma may exist.

The course of the inflammation in the injured eye (the excitor) presents no characteristic features different from those which we might expect to follow the injury, to indicate that it is to be followed by sympathetic ophthalmitis. It would be but a repetition of descriptions already given in the article on injuries of the eye, to describe the various courses of the inflammation which may follow the injury in the first eye; we have here to do only with the course of the sympathetic ophthalmitis. This much, however, may be said, that a violent suppurative inflammation (a panophthalmitis) is not so likely to cause sympathetic ophthalmitis as one of a milder and more chronic type. Indeed, von Graefe at one time advised exciting this form of inflammation, rather than allowing it to take the more chronic course with its attendant dangers. A more extended experience has since shown, however, that this advice is injudicious. In the present state of our knowledge we can simply say, that a sympathetic ophthalmitis is liable to follow an inflammation in the other eye presenting certain features. For example, the injured eye is the seat of frequently recurring attacks of an inflammation of a rather mild type, excited by no seemingly sufficient extrinsic cause. There is an area, often so small that it can be detected only by the touch of a blunt probe, which is the seat of very pronounced tenderness, and this area usually widens out with each recurring exacerbation of the inflammation. After this condition has existed for a variable period, usually of from a month to a year, the fellow-eye is liable to show symptoms that are now recognized as indicating that a morbid process has begun in it.

The time at which the symptoms may first show themselves in the second eye is, however, liable to greater variations than those reported in reply to the questions of the committee above referred to; the shortest and longest intervals were asked for, and, excluding "anomalous" or doubtful cases, they report eighteen in which the interval was less than four weeks, therefore to be regarded as short, and in four it was less than two weeks.

The longest period is more difficult of determination, as new injuries or inflammations, independent of the original injury, so frequently complicate the course of the disease that an exact statement is often impossible; excluding, however, doubtful or anomalous cases, in ten at least one year had elapsed between the injury and the first symptoms in the fellow-eye; but the literature is full of cases in which the period of immunity extended from ten to twenty years, and still longer periods. In many cases the injured eye was wholly lost and there had been no evidence of inflammation for a long time, and the symptoms in the fellow-eye started up without any recognized cause. In cases in which the fellow-eye is attacked while the injured eye is still in a condition of inflammation, it occasionally happens that the patient

and surgeon assert that they are able to refer the cause of the sympathetic attack to early use of the eyes, to exposure to bright light, etc. Mackenzie charges the disease directly to too early or excessive use of the injured eye. This, however, cannot hold good for those cases in which the fellow-eye is not affected until several years have elapsed after the injury, a period of perfect quiescence having passed over in the interim ; it is quite probable that the use of the eye has little to do with the sympathetic disease. The periods of quiescence in the remaining traumatic cases in the above report, varied between one and a half and twenty years, and this agrees with the experience of ophthalmologists in general, and means that no limit can positively be set to the period during which these sympathetic symptoms may not arise. In some cases mentioned in the report and elsewhere, secondary degenerative changes, especially calcification or ossification of the choroid, are given as the exciting cause of the sympathetic disease.

There are at present two prevailing opinions concerning the pathology of the affection. One is a development of Mackenzie's opinion of the nervous character, but instead of asserting that it is propagated through the optic nerve, this theory regards the ciliary nerves as the medium of transference. The other view is that the inflammation in the second eye is due to the presence of bacteria, which have penetrated it through the peri-vascular lymphatic system of the optic nerve. The former was the view almost universally held fifteen or twenty years ago, when the school of von Graefe was at its most brilliant epoch ; the latter is now advocated by his favorite pupil and successor, Schweigger, by Deutschman, Alt, Leber, Mooren, and many others.

As already stated, the sympathetic manifestation may occur under different forms, and in just so far does the symptomatology differ, so that a detailed description of all the clinical features must be but a description of these different, but at the same time allied, diseases; to avoid unnecessary repetition, therefore, reference is made to diseases of the iris, and uveal tract, and to diseases of the optic nerve and retina. It is necessary, however, to appreciate clinically two general classes, or stages, that of irritation, and that of actual inflammation. In its lightest form the sympathetic manifestation may be simply an irritation or an irritability on use,—a certain intolerance of light, a slight pain or weariness after reading, etc., a difficulty in fixing the eyes intently on a small object—in other words a weakness of the accommodation ; in addition there is a trifling and transitory redness of the circumcorneal conjunctiva. In other cases the intolerance of light may have amounted to entire disuse of the eyes (Donders) for many years, and yet no structural changes may have taken place, as shown by complete recovery of vision on the adoption of the proper treatment. These cases, however, of long-continued sympathetic irritation are of the rarest occurrence, and it is perhaps incorrect to include them in an article on sympathetic ophthalmitis, which of course means an inflammation with organic changes. Some writers have taken that position, but it is of the utmost clinical importance to understand that there is an initiative or premonitory stage (in these cases unduly prolonged) of a most obstinate disease, which, if recognized early, may perhaps be successfully treated ; while if this initial stage be allowed to pass on to the development of actual lesions, the result, in a very large proportion of cases, is a permanent and great impairment of vision, often total blindness. This initiative stage usually lasts but a short time, a few days or perhaps weeks, and it is quite possible that it is not thought of by the patients until impairment of vision or other decided evidences of inflammation, such as pain and redness, disturb them. An examination at this time will usually show unmistakable evidences of an iritis, the discoloration and contracted pupil being associated early with posterior synechia and blocking up of the posterior chamber. If these evidences of more advanced disease be not present, palpation, either through the closed lids with the finger, or more directly with a probe or other blunt instrument over the ciliary region, will usually show that there is a point of extreme tenderness from which the pain radiates to the rest of the globe. The statement has been made (Bowman) that this point corresponds exactly with the focus of most intense inflammation in the other eye, *i.e.*, the incision in a penetrating wound, or the entanglement of the iris and ciliary body after an operation, or the seat of the lodgement of the foreign body in the ciliary region.

The progress of the sympathetic inflammation is usually rapid and intractable to the action of remedies ; the iris fails to respond to the action of any mydriatic, the pupil becomes occluded, the posterior chamber becomes filled with plastic lymph, and the iris bulges forward at the periphery, while the pupillary edge remains adherent to the lens. The contraction of the plastic lymph effused behind the iris, over the ciliary body, and behind the lens, drags upon and separates the retina from its attachment to the choroid, lymph is effused behind it also, and it finally presents nothing but a funnel-shaped cord, extending from the optic nerve to the posterior surface of the lens. At first the globe is harder, but later, on the approach of the fatal changes, the tension diminishes, and the atrophic condition of all the interior structures is shown in the collapse, with depressions at the insertions of the recti muscles, which afterward takes place.

Sometimes the inflammation extends from the iris to the lining membrane of the posterior surface of the cornea (Descemetitis), even involving the corneal tissue proper. Lymph is deposited in more or less distinctly isolated spots (keratitis punctata), giving a mottled or dotted appearance as seen by oblique illumination. Some authors (Reindorf) describe a form of obstinate ulcerative keratitis, the ulcers which are scattered through the cornea first healing and then breaking out again, leading finally to perforations, and the eye is lost by the formation of a staphyloma of the cornea, or an irido-choroiditis with consecutive glaucoma.

Another form has been described by Warlomont and Testlin, under the title of serous iritis, coming on later than the plastic form and of slower course. "It does not affect the uveal track until after it has attacked the deeper parts. The symptoms are a contraction of the visual field, a medium dilatation and sluggishness of the pupil, and a progressive diminution of the acuity of vision. The globe becomes hard, the iris is discolored, the optic nerve excavated, and opacities form in the vitreous body. The posterior surface of the iris becomes covered with an exudation (of lymph), and filiform posterior synechiæ are produced." This is, however, a very clear picture of a glaucomatous process.

For some time after the invention of the ophthalmoscope and the consequent accessibility of the retina and optic nerve to direct observation, the opinion became quite general that Mackenzie's view of the neuro-retinal beginning in the fellow-eye was erroneous, but that the first sympathetic lesion was always in some part of the uveal track, as above mentioned. The methodical use of the ophthalmoscope in later years, however, has shown the occurrence of an initial neuro-retinitis in a much larger proportion of cases than was formerly supposed. Excluding all cases in which the retinitis could be regarded as secondary to an inflammation of any part of the uveal track (of the second eye), the statistics of the committee above referred to give about four per cent. of cases of initial neuro-retinitis in the sympathetic disease. These are all cases in which the vision was decidedly affected, and for the relief of which the patient applied to the surgeon. The percentage would be considerably increased if all cases were examined with the ophthalmoscope, irrespective of symptoms. Cases are reported in which a papillitis appears without failure of vision or other subjective symptoms, and after remaining a short period disappears again, leaving no traces. The course of the disease is sometimes an extension to the choroid and iris, with the same marked tendency to contraction in the effused lymph that is so noticeable when the process begins in the iris, etc., and in the worst cases with similar results. Judging, however, from the somewhat limited number of cases reported, it would appear that

this form of inflammation is by no means so severe as when the anterior segment of the globe is first affected; for, of the seven cases reported by the above-mentioned committee, two recovered with perfect vision, one with vision "not perfect," two with $V = \frac{6}{10}$, one with $V = \frac{3}{10}$, and in but one was vision totally lost—certainly better results than we expect to obtain in the usual form of the disease; and reports from other sources give similar results. Gepner, of Warsaw, reports an unusual case of intermittent sympathetic retinitis, coming on some three months after the injury, in which a distinct but transitory œdema of the retina was seen by the ophthalmoscope, accompanied by an amblyopia of $\frac{20}{200}$ (0.1), but all of which entirely disappeared in the course of a few hours, with a return of $V = 1$. The condition was observed by the surgeon twice—but it had existed for about two weeks before coming under observation. After the enucleation of the wounded eye the sympathetic trouble ceased entirely, and the vision remained perfect for several years, as long as the patient was under observation.

Ever since von Graefe, in 1857, described a "sympathetic amaurosis with excavation of the optic nerve" (following a spontaneous irido-choroiditis), cases have from time to time been described as "sympathetic glaucoma." Subjected to a critical analysis, however, most of them turn out to be consecutive glaucoma, the attack (of glaucoma) in the second eye following usually with a *very short* interval the operation of iridectomy made for a glaucoma of the primarily affected eye. This is not what should be understood by sympathetic disease, as has been well shown by Mauthner, Schweigger, Maats, and others. Neither are we justified in calling the condition a sympathetic glaucoma, when an eye, which has been for a considerable length of time affected with a recognized form of sympathetic trouble, such as serous iritis or irido-choroiditis, becomes glaucomatous, with plus tension and other evidences of increased inflammatory action. If the glaucoma were truly sympathetic, it should occur at the usual time after an injury to the other eye in which traumatic inflammation had been excited, and should be true glaucoma, and not merely a glaucomatous degeneration engrafted upon a preceding sympathetic inflammation. Furthermore, it should respond to the ordinary treatment of sympathetic trouble, viz., enucleation of the other eye, and not to that for ordinary glaucoma, namely, iridectomy on the eye affected. Unfortunately for the determination of this question, the surgeon, feeling the importance of leaving nothing untried for the relief of so imminent a danger to his patient's vision, carries out the enucleation of the excitor and the iridectomy on the sympathizer at one sitting, so that it is impossible to say to which the good result, if it occur, be due. Nevertheless, the facts observed in certain cases of Webster and Agnew, and of Dobrowolsky, lend considerable weight to the glaucomatous interpretation. These and other cases, such as those of Camuset and Krachner, of sympathetic cataract, and of Barbier, Krause, and von Graefe, of choroiditis disseminata, in which the history points apparently very positively to the sympathetic origin, must be classed among the very exceptional cases to which the explanation usually given of the pathology does not apply, and which seems to show that we have not yet demonstrated all the channels for the transmission of sympathetic disease.

Mackenzie's interpretation of the symptomatology was that it was a "reflex" inflammation, carried from the injured to the sound eye directly along the optic nerve; therefore that it was primarily a neuro-retinitis in the fellow-eye. This remained the general opinion until the discovery of the ophthalmoscope, bringing the fundus of the eye directly under observation, showed that the posterior segment of the globe was quite free from disease, at least so long as the media remained clear enough to allow it to be seen, and that the initial evidences of disease were confined to the anterior segment. Confirmatory of this ocular demonstration as to the non-participation of the optic nerve, an accurate study of the clinical phenomena soon showed that instead of this being the nerve along which the disease travelled, the ciliary nerves throughout were the medium of conduction of the sympathetic trouble. The organs or tissues to which the corresponding nerves are distributed are the seats of the initial lesions in the fellow-eye; the nerves are presumably the means of communication to it. The clinical evidence already recited seems to be quite complete; the view has received the almost universal acceptance of the profession, and the results of therapeutical procedures based upon this view confirm it.

The interpretation of clinical phenomena is, of course, a speculation based upon evidence which must in legal phraseology be designated as circumstantial, and must always be open to the admission of new facts, as new cases or new methods of investigation are brought to bear upon it. As previously stated, investigations in bacteriology have made this, the isolated example of an asserted "sympathetic" inflammation, the object of considerable study, with the result of establishing a possibility amounting, they claim, to proof, that there is an infectious element (micro-organism) concerned in the propagation of the disease. To exactly what extent the bacteria are related to the disease, whether they are essential to the production of the various phenomena observed, or whether their presence be simply accidental and of no importance, are, however, points which are still to be regarded as *sub judice*.

Deutschmann, in a series of experiments extending over several years, has studied the effects upon the fellow-eye of the introduction of micro-organisms and of irritating substances into the vitreous body and into the optic nerve-sheath. His experiments were all made upon rabbits, and he gives the following as the results of his investigations: 1. The injection of aspergillus, of croton-oil, or of staphylococcus aureus and albus, was uniformly followed by papillitis, neuro-retinitis, and choroiditis of the fellow-eye; 2, the process can be traced by post-mortem examination along the sheath of the nerve, starting from the seat of the injury; 3, in the case of the bacteria, similar organisms to those injected, and those only, are found in the secondary lesions. The progress of transmission from one eye to the other is a matter of several weeks, though the amount and the strength of the injection (depending upon the dilution of the injected fluid with a saline solution) influence greatly the rapidity of the transmission.

Besides the experimentally excited sympathetic disease, Deutschman also reports the results of examinations of eyes which had caused sympathetic inflammation in their fellows, and which had been enucleated as a therapeutic measure. In all he found micro-organisms and the extension of inflammation along the nerve and sheath as far as the specimen allowed examination. He thinks it probable that there are various micro-organisms capable of producing sympathetic ophthalmitis; in other words, that it is not a specific inflammation. In answer to the objection that purulent micro-organisms usually excite an acute (virulent) process, he denies that this is constantly the case, and cites an instance of experimental disease in a rabbit inoculated with a culture fluid of staphylococcus albus, obtained from the anterior chamber of a patient suffering from sympathetic ophthalmitis. At the end of five weeks the rabbit's eye showed beginning atrophy of the optic nerve, an opaque white disk, strikingly narrowed vessels, atrophic nerve-fibres, and all the evidences of an essentially chronic non-suppurative inflammation.

For these reasons, and from a consideration of the results of other experiments and clinical observations, the bacterial nature of sympathetic ophthalmitis has been accepted by many ophthalmologists of authority. Schweigger, Leber, Snellen, Mooren, Alt, Mules, and others have put themselves unreservedly on record as believing this to be the best explanation of the intricate subject of sympathetic ophthalmitis.

To the writer, however, the view has not presented itself so convincingly; the progress of bacterial infection elsewhere in the human subject is so much more rapid than in sympathetic ophthalmitis, and the course here is so different from that of other well-authenticated septic

(bacterial) infections of the eye, as in metastatic choroiditis and retinitis, that it seems to be going too far, for the sake of a theory, to regard the processes as essentially the same. The advocates of this view apparently ignore also some very important clinical facts that should be regarded as characteristic of the disease. In order to establish their theory, they insist upon an essential difference between sympathetic irritation and sympathetic inflammation, asserting that the former never passes into the latter, and that if it remains in the irritative stage there is no propriety in calling it sympathetic inflammation. As has already been stated, among the clinical facts which first direct the attention of the patient to his eye, and for which he first consults the surgeon, is a certain, perhaps trifling, photophobia, lachrymation, and pain on use; as the patient usually expresses it, his eye gets tired easily, and if the disease be unrelieved after a variable time, and perhaps after repeated attacks alternating with apparent recoveries, a pronounced inflammation sets in. These facts are undisputed, and the claim that the irritation is but a premonitory stage to the inflammation is certainly not a forced one.

The uncertainty of the time of the appearance of the inflammation in both the injured and the sympathizing eyes, varying, as it may, from a few weeks to even forty years after the receipt of the injury, argues against the microbial theory. And the fact that in one set of cases there may be repeated attacks of irritation, while in another set the original wound may heal, and the eye may remain in a quiescent condition for years, the inflammation starting up then, with no new wound (or it may even be that the injured eye takes on no fresh action, but the fellow-eye becomes inflamed and goes through the stages of iritis, irido-cyclitis, or neuro-retinitis, to the loss of a greater or less degree of sight), is inexplicable by any theory of constant bacterial infection, but is quite reconcilable to the nervous view. If the bacteria were introduced at the time of the injury, what has prevented their development during the years of quiescence of the eye? If present at all, they were always in the same culture medium, and wherefore then this long delay, and what is the cause of their sudden activity? There can be no change in the culture medium but that which has already taken place many times before during the long period of inactivity.

These well-established clinical facts do not harmonize with the bacteriological theory, while there is nothing to disprove the opinion, gradually developed through years of observation of the clinical phenomena, that the sympathetic inflammation is brought about by a neuritis of the ciliary nerves of both eyes, caused in the first eye by the entanglement of the terminal fibres in the cicatrix of the wound, propagated thence to the fellow-eye. This propagation may be by way of the ciliary nerves, and through the medium of the ophthalmic ganglia of the sympathetic nervous system and the vaso-motor nerves, to the ciliary nerves of the fellow-eye, there exciting trophic disturbance in the tissues to which the nerves are distributed, and giving rise to the various inflammations of the anterior segment of the globe above described; or the irritation may be transmitted more directly by the optic nerves to the posterior segment, giving rise to the neuro-retinitis described. The former is the common mode, the latter the exceptional.

The writer is aware of the indefiniteness in the description of the extension of the inflammation through the medium of the sympathetic system; so also is our knowledge of the physiology of this system indefinite, but it is doing no violence to our knowledge of the action of this complex system to assume this much.

There is also a certain analogy (not identity) between this sympathetic process and those trophic changes observed in distant parts following severe injuries to the main nerve-trunk. The observations of Mitchell, Morehouse, and Keen have shown that there may be very general changes of the tissues to which the nerve is distributed, evident especially in the skin and its adnexa, and the joints, although the muscular, osseous, and cellular tissues may all occasionally show grave changes. In the joints (arthropathies) the evidence of an inflammatory process is shown in a painful swelling, a slight redness about the articulation, extreme sensibility, and finally, persistent rigidity and a semi-anchylosis which resists all treatment. When the acute stage has disappeared the tissues around the articulation are indurated, and there results a partial anchylosis. In the skin there is a peculiar, glossy redness or erythema, there may be eruptions of different kinds, the glands disappear, etc. Mitchell has shown that these trophic disturbances follow incomplete sections, contusions, punctures of a nerve—in other words, causes which determine an irritation of a nerve rather than its complete local destruction. It seems to me that we are justified in believing that the conditions which pertain in sympathetic ophthalmitis bear a sufficiently strong resemblance to those of nerve-irritation, and consequent trophic changes, to justify us in accepting this in preference to the bacteriological theory.

The intractable nature of this disease, and its obstinacy in resisting treatment have already more than once been referred to. Mackenzie was led to seek for a reason for the fact that a certain number of cases of ophthalmitis, beginning apparently in a mild way, were so excessively obstinate in their resistance to modes of treatment which were fairly successful in other cases. He noticed that they were all associated with an injury to the other eye, and he then grouped them into the class we are considering. The futility of all the ordinary methods of treatment for sympathetic iritis and its complications, as well as for neuro-retinitis of sympathetic origin, was early recognized. Although the observation of a greater number of cases has shown that *all* do not run an absolutely unfavorable course, still instances of this kind are exceptional, and we should regard every case that presents itself as threatening total blindness of that eye, even though a considerable degree of vision may remain in the injured eye.

In 1857 Dr. August Pritchard, of Bristol, England, recognized the importance of relieving the sympathizing eye of the source of the irritation by removing the injured eye entirely, when vision in it was totally lost. This operation (enucleation, Arlt), was followed by a relief of the inflammation in the fellow-eye, and has ever since been acknowledged to be the most promising means of combating this so fatal disease. Although a wider experience has shown its limitations, it or its modifications may still be regarded somewhat as a specific for this unique form of inflammatory action.

The uncontrollable tendency in the plastic material thrown out in the inflammation of the uveal tract, to contract after the active stage has passed, the contraction being as certain as that following deep burns of the skin, shows the importance of getting early control of the disease before the plastic lymph has been effused. And the results of the operation show that, to be of much benefit, the enucleation must be performed either as a prophylactic measure, before any evidences of irritation or inflammation have shown themselves, or during the irritative stage, before organic changes have taken place. If performed after inflammation has fairly begun, while it may possibly mitigate the severity of the process, it seldom saves good vision; the secondary (cicatricial) contraction usually produces such a fusion of iris, lens, capsule, and ciliary body that no subsequent operative interference is of avail. It is still doubtful, if the enucleation be delayed, whether it mitigates the ophthalmitis at all; occasionally it seems but to add to the severity of the symptoms, the subsequent course being even more rapid than before.

The importance of an early operation, if it is to be done at all, is, therefore, very great, and the question of probability of sympathetic ophthalmitis occurring at all is of the utmost importance; for while there can be no doubt as to the advice to offer when the question is distinctly between total blindness and mutilation, when it is simply between mutilation and a more or less remote chance of blindness patients will always hesitate and often decline the operation. Statistics are wanting as to the exact proportions between all injuries and sympathetic

ophthalmitis; but, as has been stated, injuries of the ciliary region, causing the entanglement of the iris, ciliary muscle and processes, and choroid, "especially if there be loss of vitreous" (Mackenzie), and foreign bodies remaining in the globe, whether the penetration be through the ciliary region or not, are all such constant sources of danger that *if the vision be destroyed* the surgeon should take the responsibility of advising the removal of the eye. The sooner this is done in such cases the better, usually, though in childhood the enucleation is liable to check the normal development of the orbital cavity and produce a greater deformity than if it be practised after the bones of the face have attained nearly their full development.

Whether the globe should or should not be removed during active suppuration has been discussed in the article Panophthalmitis, but the necessity is not so great on account of the sympathetic dangers as of relieving present suffering. Leaving for a moment the question of the effect of this operation on the preservation of vision in the fellow-eye, it must be remembered that there is still a positive, though fortunately but very slight, danger to life in the operation for removal, even without a panophthalmitis; deaths have followed from meningitis or from shock in several reported instances, and in how many unreported cases no one knows.

If there still be vision, or a remote prospect of saving some, the wound being in a dangerous situation, the problem becomes more difficult of solution, for, if the patient wait for symptoms in the fellow-eye, he may delay too long, or the irritative stage may be so rapidly followed by the inflammatory process that the operation is useless; and yet neither surgeon nor patient wishes to sacrifice an eye there is a prospect of seeing with. Furthermore, there have been unfortunate cases in which the enucleation itself has seemed to precipitate, if not cause, the outbreak of the sympathetic disease.

Recognizing, as we must, the double path of the disease from one eye to the other, it is evident that if the disease be of the neuro-retinal form, and have advanced along the optic nerve to a distance beyond the point of division, the operation is likely to be an additional irritation to the already inflamed tissue, and may readily be sufficient to cause the loss of the fellow-eye; and if there be a bacterial influence at work there will be a better chance for the introduction of the germs.

Undoubtedly many eyes with some useful vision in them have been sacrificed to the fear that the fellow-eye may become affected; but the converse is also true, and many more eyes have been lost and total blindness has resulted by reason of the repugnance to submit to enucleation. The surgeon is at fault in the former case, the patient usually in the latter.

If the patient can be depended upon, as most persons of intelligence may, the operation may be postponed, with the express understanding, however, that he will report immediately upon the appearance of the *first* symptom of irritation, such as lachrymation or other difficulty in the use of eyes for near work, photophobia, or phosphenes (photopsia), when the surgeon must determine whether there is any danger of an increase of the process, or may detect by the ophthalmoscope the presence of optic neuritis (papillitis) or choroidal trouble. In the presence of any positive evidences of disease, however slight, the operation must be advised. If the injured eye is the seat of chronic inflammation, with periods of exacerbation, it should be removed; or, if the patient first presents himself with the history of repeated slight attacks of irritation in the fellow-eye, the removal of the injured eye should be advised.

The history of the enucleation in those infrequent cases of serous iritis or of glaucomatous processes, does not warrant so favorable an opinion of its utility. Why this should be the case it is difficult to say, but the observations seem to be fairly uniform and may be regarded as an argument against the existence of a sympathetic glaucoma. Mauthner has formulated his opinions on the advisability of enucleation as follows: It *may* be performed as a prophylactic measure; it *must* be done in the irritative stage; it *must not* be performed in active iritis, serous or plastic; it *can* be done in irido-cyclitis (the sympathizing eye being quite blind and not in a condition of active irritation).* While rules thus positively stated are legitimate subjects of criticism, they may be regarded as representing in the main the general views of ophthalmologists of the day.

In view of the natural repugnance of the patient to being subjected to so severe a mutilation, and of the surgeon to being compelled to inflict it, ophthalmologists have sought to devise some means to accomplish the separation of the injured eye from its fellow, in which this objection would not apply. Regarding the nerves, optic and ciliary, as being the media of transmission of the morbid influence, von Graefe advised and practised the division of these nerves behind the injured eye, and for several years afterward the bibliography of ophthalmology was plentifully strewn with reports of optico-ciliary neurotomy and its effects, and although the authors continued to report successful cases, that is to say, cases in which disease did not develop in the fellow-eye (prophylaxis), or in which the eye was benefited, the practical demonstration of the benefit of the operation, its general adoption by the profession, is yet wanting. The uncertainty of being able to make successfully the division of the ciliary nerves has always stood in the way of the surgeon's ability to guarantee to the patient a relief from the threatening blindness with as much confidence as he could were enucleation to be performed. The operation has never received an equal degree of sanction by the profession as has enucleation, and has gradually fallen into comparative disuse. It is, however, to be proposed as a tentative procedure in cases where the repugnance to removal of the globe cannot be overcome, but if the symptoms return or persist, the enucleation must be performed later.

The neurotomy may be performed with or without division of the rectus muscle; there is not much choice between the external and internal. If performed without division of the muscle, a longitudinal incision, parallel to and just above the upper border of the external rectus muscle, is to be made through the conjunctiva, a pair of long-bladed scissors, curved on the flat, are introduced, and then all the short ciliary nerves external to the optic nerve are freely divided. A strabismus hook is next introduced, and the optic nerve is seized and drawn as far out of the wound as possible, thus rotating the globe on its vertical axis and turning the cornea inward. This allows the nerve to be cut off far back in the orbit, when the portion attached to the globe may be seized with the forceps, the globe reversed further yet, and the piece of the nerve still attached removed close to its entrance in the globe. The ciliary nerves internal to the optic nerve are now accessible and must be entirely removed.

The division of the muscle allows freer access to the posterior part of the globe and secures a much more certain division and resection of the nerves, both optic and ciliary, and the operation is thus more readily carried out, but a considerable strabismus is apt to remain. To avoid this it is well before dividing the muscle to pass a thread through it and after the neurotomy has been performed to stitch it again to its place.

Either of these operations, and especially the latter, has the very serious objection of being liable to be followed by considerable hæmorrhage, which, by filling the orbit, pushes the eyeball forward (exophthalmos) and is sometimes followed by such severe and uncontrollable pain as to require the enucleation after all,—a condition of things which can but tend to aggravate the disease sought to be relieved.

Is there any other treatment than getting rid of the source of the irritation which is of avail? Can anything be done to check the progress of the disease in the sympathizing eye itself? But little; though no surgeon could feel himself justified in making no attempt to save an eye thus affected, however hopeless he may think it.

* The exact meaning of the last sentence, "it *can*," etc., is not altogether clear unless it be that the injured eye is to be removed to relieve intolerable pain, even if the sympathizing eye be blind; otherwise the word sympathizing is a misprint for injured.

In iritis and irido-cyclitis the instillation of atropine must be persistently carried out. By its paralyzing action on the iris and ciliary muscle, it keeps them at rest, thus alleviating pain and tending to reduce inflammatory action, and it may happen that the iritis will subside while the pupil is dilated and before it becomes blocked up with lymph. Leeches may be applied to the temple, or if these be unobtainable Heurteloup's or some other form of artificial leech, with cupping, may be substituted. With the idea that mercury checks adhesive inflammation some form of this drug may be administered to the production of gentle salivation. These are the routine remedies in general use, and their good effects are not to be ignored or underestimated, but neither is the surgeon justified in building much hope upon them in either his own or his patient's mind. I have seen an iris which was fully dilated with atropine in the early stages of sympathetic ophthalmitis, the patient being kept on the verge of poisoning with it, gradually contract day by day; lymph continue to be poured into the pupil, the latter become hopelessly blocked up, the iris bulge forward, and total blindness ensue, in spite of the atropine, mercury, and leeches. In other cases, milder usually from the start, this treatment occasionally seems to be followed by such amelioration of the symptoms that the surgeon cannot but hope that the next case will prove equally responsive to his treatment. These are, however, the exceptions.

The results of operative interference in the acute stage are usually disastrous. An iridectomy is almost surely followed by an increase of the iritis. It is not until the eye has been entirely free from inflammation for several months, and when there is also good reason to believe that there is no detachment of the retina or other lesion of the fundus—that is, that the acute inflammation was confined to the iris and the changes which followed were merely incident to this,—that, in cataract with closed pupil and a blocking up of the posterior chamber, a broad iridectomy, with simultaneous or successive extraction of the cataract, may be made. In all probability successive lacerations and removals of false pupillary membranes and membranous deposits behind the iris, with repeated iridectomies, will be required. If it be necessary to repeat any operative procedure, or if successive operations be required, time must be given between them to let all inflammation subside. These operations are described in other parts of this work under the proper heads of Cataract and Iridectomy, so that it is unnecessary to repeat their description here.

Addendum.—Through the very great courtesy of Professor William H. Welch, of Johns Hopkins University, and Dr. R. L. Randolph, of Baltimore, Md., I am enabled to give here, in advance of publication elsewhere, the results of a series of attempts to verify Deutschmann's experiments on the production of sympathetic ophthalmitis in the lower animals.

"The experiments were performed upon dogs. Four or five drops of a solution of staphylococcus pyogenes aureus were injected into the corpus vitreum, using for this purpose a hypodermic syringe which had been previously thoroughly sterilized, taking especial care that none of the solution came in contact with the edges of the puncture, thus avoiding, as far as possible, the inoculation of the surrounding tissues, and setting up a general inflammation. Clouding of the vitreous was observed in every instance an hour after the operation. In twenty-four hours the fundus was no longer to be seen. In every case but three, panophthalmitis ensued, followed by rupture of the eyeball and disorganization of its contents. In the three cases mentioned the eye recovered after a severe kerato-iritis, which left the cornea clouded and deposits upon the anterior capsule (of the lens). The pupils, however, responded to light, showing that the optic nerve-fibres possessed functional activity. It was impossible to see whether the fundus had participated in the inflammation. Examination of the uninjured eye with the ophthalmoscope revealed in every instance a perfectly normal fundus; not even did the blood-vessels of the retina show anything that would suggest that they sympathized with the condition existing in the inoculated eye.

"The dogs were all killed at periods varing from twenty days to three months. On examining sections of the inoculated eyes, dense, round-celled infiltration was seen throughout the coats, in which the papilla participated. In several the inflammation extended to within half an inch of the chiasm. In only one case did the neuritis reach the chiasm, and then it was confined and stopped on that side of the chiasm adjacent to, and continuous with, the optic nerve of the inoculated eye. *The presence of organisms in the tissues of the eye, or optic nerve, of the side not inoculated was never detected.*

"This is the first time that dogs have been used for experiments of this nature. It is possible that they possess an immunity from sympathetic ophthalmia, or that we are not apt to have the disease when the eyeball ruptures, though the case in which the inflammation was seen in the chiasm happened in a dog whose eye had ruptured forty-eight hours after inoculation. In this case, however, the inflammation must have spread from continuity and exhausted itself by the time it reached the chiasm. Certainly if the cocci had been the *causæ morbi*, there is no reason to think that they would have lost vitality after reaching the chiasm. The same reasoning would apply to the other cases where the inflammation had travelled some distance up the optic nerve."

Comment on these experiments is superfluous on my part. I allow myself, however, to say this much: I was entirely unaware that they were in progress until after the above article was finished, and I then learned of them through my friend Dr. Theobald. I am, of course, pleased to be able to confirm the views I have expressed, which were derived from a study of the clinical phenomena, by the negative results of experiments carried on by such competent authorities.

SYMPHYSIOTOMY. Delivery of the fœtus by pubic section, in cases of pelvic deformity, was devised in 1768, by Jean René Sigault, a French medical student, who sent the proposition to the Academy of Surgery of Paris, by the members of which it was regarded as the wild scheme of an ignorant youth. Not regarding this stamp of disapproval, he made it the subject of his thesis at Angers, in 1773. In so far as his method was designed to apply to the living woman in parturition, it was original with Sigault, but it had twice been tried upon the dead woman. The first operation upon a woman who had died in labor was performed at Warsaw, in 1655, by Dr. Jean V. C. Delacourvée, of France, then in practice there, the subject, aged forty-eight, having been in labor four days; and the second was in 1766, under Professor Jos. Jacques Plenck, of Bude, Hungary, for the liberation of a locked head in a post-mortem Cæsarean section. It does not appear that it ever entered into the thoughts of either of these obstetricians that such an operation might be of value in the cases of living women.

After his graduation Dr. Sigault embraced an early opportunity of carrying his scheme into effect, and on October 1, 1777, performed the initial operation, upon Madame Souchot, a dwarf of three feet eight inches in height, and delivered her of a living child, having a bi-parietal diameter of three inches and one line. The pelvis measured in its true conjugate, two inches and three-quarters (Eng.), and the child presenting by the feet was readily extracted. This was the fifth pregnancy of the mother, and her first child delivered alive. A permanent disability resulted from the use of the knife, in the form of an incontinence of urine.

The result of this case, although in a measure imperfect, and not a fair test of the value of the operation, because of the working space, three inches, in the superior strait, gave great credit to the operator, much to the annoyance of the Academy of Surgery, by which it had been condemned nine years before. Not content with a moderate degree of praise upon the test of one operation, Dr. Sigault was lauded as a public benefactor; a medal was presented to him by the Faculty of Medicine, and the government granted to the operator and the patient —the latter the wife of a soldier—each a pension. This excess of adulation created a feeling for and against the operation, in which the Academy of Surgery took an active part; and as it was claimed that the pubic section was to take the place of the Cæsarean operation, the medical profession became divided into *Symphysiotomists* and *Cæsareanists*, each advocating the one plan of delivery to the disparaging of the other. The basis of the scheme of Sigault was the claim that relaxation of the pelvic synchondroses took place during the latter months of pregnancy, and it was only requisite to open the pubic symphysis by the knife, after which the sacro-iliac junctions might be made to move like a hinge, and admit of a wide separation at the point of section, without strain or injury of the posterior synchondroses. This measure of relaxation was denied by many, upon the results obtained by experiments anything but crucial, made upon dead bodies, under which the ligaments tore. Years later, when the excitement was over, and the operation rarely performed, experiments properly conducted, and without prejudice, under Dr. Girard, of Paris, in 1800, and Dr. Ainsiaux, of Liége, in 1811, elicited very different results. The bodies of women who died in labor were used as subjects of the test, and it was found that when operated upon soon after death the mobility of the pelvic bones upon each other was quite marked, and would admit of a wide separation at the pubes without laceration. Dr. Ainsiaux obtained, under these circumstances, as much as three inches; but found that when a woman had been dead thirty-six, thirty-eight, forty-eight, or fifty-four hours, he could only separate the bones one and one-half to one and one-fourth inch without laceration.

The original Sigaultian operation was very simple in its method of execution, but was liable to accidents, from the knife incising too deeply behind the symphysis, or through the pubic arch, or not taking the central line of junction between the pubic bones, but cutting a piece from one of them, leading to a delayed union, with perhaps escape of a fragment of bone.

In the year 1778 the operation was fairly inaugurated, as it was performed eleven times, under eight operators,

in Germany, France, Belgium, and Bavaria, four of the sections having been the work of Sigault himself, who ended his experience, after having had five cases, with four women and one child saved. Under the whole eleven operations of the year, six women were saved, and ten children were lost. This was certainly not very encouraging for an operation designed to save two lives and to supersede the Cæsarean section, if not entirely, at least in large measure. Too much was expected of the operation, and attempts were made in cases where the pelvic contraction was entirely too great for success. Sigault failed, on this account, with his fifth and last operation, which was upon a dwarf of thirty inches high, pregnant with a fœtus twenty inches long, and having a conjugate herself, computed at twenty-two or twenty-three lines. She died of pelvic injuries in five days. This failure appears to have put a check upon his ambition, and he subsequently declined to test his method upon a woman having a two and one-half inch conjugate. Pelvic injuries and fœtal death appear to us now to have largely resulted from the method of delivery usually adopted—the child being turned and its head drawn through the superior strait, thus forcing open the sacro-iliac symphyses, and destroying the fœtus at the same time.

In the second year of the operation (1779) there was a falling off in numbers to four, saving all of the women and two children, the cases being all in France, and two of them under the care of Dr. Alphonse Leroy, who became an early advocate of the operation, and performed it during a period of twenty-six years, his last delivery under it being in 1804. Leroy operated in this period only five times, but is twice recorded as having assisted others. Four of his own patients recovered, and three children were saved; two others were delivered in a moribund state, both by the feet.

In 1780 there were but two operations as far as recorded, and the same in 1781; after which they varied in numbers from one to four each year until 1840, between which and 1858 (when they ceased, with two fatal exceptions in Bologna, in 1863 and 1865, until the revival of the method in a much less fatal form in Naples, in the year 1866) there were but six cases.

From 1777 to 1866, the year of the revival referred to, there were 86 operations, of which the results have been recorded; a few others have been mentioned, but no particulars given. Of the 86 women, 57 recovered, and 29 died; 45 of their children were delivered dead; 6 in a dying condition; the fate of 6 is not mentioned, and 29 were saved. It is evident that the operation gradually fell into disuse, largely on account of its failure to save the lives of the children.

The subcutaneous method of incision was introduced at Utrera, Andalusia, Spain, on August 9, 1780, by Professor Francisco Canivel, of the University of Cadiz, who directed an operation performed by a licentiate, Amonio Delando. The case was that of a primipara, aged forty-two, in labor three days, and was the eighteenth operation in chronological order. As is done in Naples with so much success at the present day, the incision was made from below upward, and from within outward. The woman recovered in thirty-eight days, and the child was saved. Cazeau, very erroneously, credits the initiation of this method to Dr. Imbert, of Lyons, who recommended it in 1833, fifty-three years after its first successful performance.

Symphysiotomy was first performed in Italy by Dr. Antonio Lavaguigno, of Genoa, on December 24, 1781, upon a subject having a conjugate of 65 mm. or $2\frac{9}{16}$ inches. The fœtus presented by the head, and being thought dead, was extracted with a crotchet, and lived several hours. The woman died in seventeen days, her external and internal parts being gangrenous. This destructive condition of the soft parts appears to have been a not unusual sequel of the operation of Sigault in its early days, particularly in cases of extreme pelvic deformity, where tractile force, rather than nature's process of extrusion, was relied upon for the delivery of the fœtus. Symphysiotomy was first performed in Naples, in 1787, by Professor Domenico Ferrara, upon Vittoria di Montesarchio, who recovered, but in whom the symphyses failed to unite. She was living and able to walk twenty years later, being employed as a messenger; her child was lost.

Between the operation of Ferrara and that of Jacolucci, on July 25, 1858, when the old period may be said to have closed upon symphysiotomy in the city of Naples, there were performed in that city, including the two named cases, twenty-seven operations, of which sixteen were under Professor Genaro Galbiati, who was the inventor of the strong curved button-ended bistoury (falcetta) in use at the present day in making the subpubic section. Galbiati's operations were largely upon pelves having a $2\frac{9}{16}$ inch conjugate, and hence a very severe test of the method. Eight were of this measure; two were of $2\frac{1}{2}$ inches; three were of $2\frac{3}{8}$; three were malacosteon deformity; and in one, the conjugate was reduced to 51 mm., or only 2 inches; this last died undelivered. Eight of the women were saved, and but four of the children. The whole twenty-seven Neapolitan operations saved sixteen women and ten children.

Failing to obtain from the operation of Sigault the advantages of the Cæsarean section in cases of extreme pelvic stenosis, Professor Galbiati devised and executed, in 1832, the murderous operation known as *bipubiotomy*. Having a pregnant dwarf under his care, $3\frac{1}{2}$ feet high, with a conjugate of only an inch, he conceived the plan of opening her pelvis like a bellows, by disconnecting its anterior from its posterior portion, by a subcutaneous section made with a chain-saw through the horizontal and descending rami of the ossa pubes on either side. This scheme he put into execution on March 30th of that year, and delivered the woman of a dead fœtus, but such was the injury inflicted on the mother that she died in agony four days later, her vulva, vagina, and surrounding tissues being all gangrenous. Not contented with this test, Dr. Nanziante Ippolito repeated the experiment in the *Ospedale dei Incurabili*, ten years later, with a similar fatality; and recently we have noticed a proposal in Europe, by some one who must be ignorant of what has been already done, to make trial of this murderous and unscientific measure.

Since the year 1818 symphysiotomy has had its home exclusively in Italy, and but very few operations have taken place outside of the city of Naples, in whose Hospital for Incurables the work has been chiefly done. In 1858 it entirely died out even there, and for a period of eight years there was not an operation. Rachitic deformity being quite prevalent, and there having been lost over ninety-two per cent. of all of their Cæsarean cases in seventy-five years, although all of the children were delivered alive, the medical staff of the hospital felt called upon to do something to lessen this fearful mortality, and, strange as it may appear, her obstetricians chose to revive the much-abused and destructive operation, especially to children, of Jean René Sigault; and the work recommenced on January 5, 1866. By the use of the subcutaneous method of incision, and the avoidance of version, or any unnecessary tractile force, it was soon found that the fœtal head would slowly expand the superior strait, become moulded to its form under the contractions of the uterus, aided by the expulsive efforts of the mother, and finally extruded without material injury to the sacro-iliac synchondroses, or causing the death of the fœtus, except in small proportion. Since the above-named date the operation has been performed in Naples 76 times, with a saving of 57 women, or seventy-five per cent., and 58 children, or $76\frac{7}{38}$ per cent. In these are included two operations where labor was induced in the seventh and eighth months respectively, saving both women and one child; and one in which the fœtus being dead, and the conjugate under two inches, the superior strait was enlarged by separating the symphysis, and the fœtus was then delivered under craniotomy. The woman recovered in forty-two days. Professor Novi, who performed this operation, on September 8, 1872, doubted the propriety of risking the Cæsarean section for the removal of a dead fœtus, which being of full size could only be removed

by craniotomy alone, at great risk, through so narrow a pelvis. He has had three craniotomy cases since.

The association of symphysiotomy with the induction of premature labor, in the cases of rachitic dwarfs having very small pelves, is well illustrated in the following record, and by photographs sent to me from Naples. Probably the operator at the present day would weigh the question of performing the Sänger operation at term. Lucia Esposito, a rachitic dwarf, aged twenty, and 3 feet 7¾ inches high, having a true conjugate of $2\frac{3}{16}$ inches, entered the obstetric clinic of Naples on May 15, 1880, in the seventh month of her pregnancy. When the extent of her deformity was ascertained it was determined by Professor Ottavio Morisani to bring on her labor in the first week of the eighth month, and this was accordingly done on June 9th. On June 11th, labor being sufficiently advanced, the symphysis was opened, and the fœtal head, which presented by the vertex, began to descend, passed into the pelvic cavity, met with some delay at the perineum, and was finally extruded. The fœtus began soon to breathe regularly; it weighed 4¼ pounds; measured 15¾ inches in length; occipito-mental diameter, 4⅜ inches; biparietal, 3 inches; occipito-frontal, 3½ inches; and bitemporal, 2⅝ inches. The child, when three days old, was sent to a foundling hospital. Being in summer, the wound was treated by irrigation, and at the end of a week by an immovable apparatus for fixing the pelvis, an opening being left over the wound. Union was complete in thirty-four days, and the patient left her bed in forty, being soon able to walk without pain or inconvenience.

In the early days of Sigault's operation the main contention was upon the measure that might be gained in the sacro-pubic diameter by each inch of separation of the ossa pubis, and the amount of injury to the sacro-iliac synchondroses that must be inflicted by the forcible separation of the innominata. Since the revival of the operation the value of slow separation and head-moulding have been considered, and the gain in the transverse and oblique diameters found of great importance to the passage of the head. Careful and accurate pelvic measurements must be made, and the operation should not be undertaken where the conjugata vera is less than 67 mm., or 2⅝ inches. The operation is best adapted to the symmetrical rachitic pelvis. If there is any asymmetry, extra care must be taken in finding the anatomical centre of the symphysis, so as to avoid slicing off the end of one os pubis, as has several times happened, in which event the exsected piece will become carious and a fistula will remain until it is discharged or removed. The operation is not admissible where disease has affected one or both of the sacro-iliac symphyses, as in the oblique pelvis of Naegelé, or the still narrower and anchylosed one of Robert. In the flat-sided pelvis produced by coxalgic anchylosis of one hip-joint, where one ilium is undeveloped, there is apt to be a bony union between the sacrum and ilium, making pubic section unavailable.

The amount of separation usually obtained in the operations at Naples, 50 mm. (2 inches) it is claimed, may be secured without risk of injury to the sacro-iliac symphyses. Version should not be resorted to when the head can be made to engage. The forceps have been applied in about one case out of four. Under the first fifty operations in the *Ospedale dei Incurabili* of Naples (1866–1880) vesico-vaginal fistula was produced in but one case, which was easily cured by an operation. Firm union of the symphysis pubis was secured in the cases of the 40 women who were saved out of the first 50 operated on, and Professor Morisani has assured me that these women had good health after the operation. Of the 50 fœtuses delivered, 46 presented by the vertex, and 42 of these were alive on removal.

CAUSES OF DEATH.—In 19 Neapolitan subjects the causes of death are thus recorded: Metro-peritonitis, 3; septic metro-peritonitis, 1 (endemic in hospital); iliac phlegmon and metro-peritonitis, 1; peritonitis, 2; endocarditis, twenty-four days after operation, 1; endocarditis and diphtheritic vaginitis, 1; puerperal infection, parametritis, pelvic abscess, and tetanus, 1; gangrenous endometritis, 1; long labor and repeated application of forceps prior to section, 1; long labor and pelvic tumor, 1; labor three days, fœtus dead, *operation unjustifiable*, 1; *operation unjustifiable*, fœtus dead, c. v. $3\frac{3}{16}$ inches, 1; *the same*, labor induced, fœtus dead, c. v. 74 mm. (nearly 3 inches), 1; not stated, 2.

The history of symphysiotomy not only embraces two entirely distinct periods, but its prognosis is signally changed as regards the mother, and much more decidedly so in reference to the fœtus in utero; in fact, an entire revolution has been produced in the second period, as compared with the first. This is shown not only in the diminution of the death-rate, but in the causes which lead to death. I have given those since 1866, and will now mention some taken from the records of the eighteenth century, viz., external and internal gangrene, pelvic injuries, gangrene of the genitalia, intrapelvic parts found gangrenous, etc. Fœtal death has largely diminished since version and traction by the feet have become the exceptions in practice. Now the fœtal mortality is twenty-four per cent., and was but 18 out of the first 50, commencing in 1866. In the old period about five fœtuses out of eight were either dead or moribund when extracted.

DISTRIBUTION OF CASES.—Symphysiotomy has never been performed in the United States, and only once in Great Britain. In Italy there have been 115 operations; in France, 32; Holland, 6; Belgium, 4; Germany, 3; Spain, 1; England, 1; total, 162; it is said also to have been performed in Constantinople—no results have as yet been found reported.

Symphysiotomy can never take the place of gastrohysterotomy in cases of extreme pelvic stenosis, as by general consent among operators the minimum available conjugate has been fixed at 67 mm., or 2⅝ inches. Of 68 cases reported by Professor Ottavio Morisani, Director of the Obstetric Clinic of Naples, only 2 were under this measure; 18 gave the 67 mm., and the balance ranged from 68 to 81 mm., there being 20 at the last computation ($3\frac{3}{16}$ inches). There were five deaths at each measurement, *i.e.*, 67 and 81, and eight at the intermediate points.

Thus it will be seen that the operation of Sigault has a conjugate range of a fraction over half an inch, and covers the ground within which craniotomy can be most safely performed. Executed with the care and skill of a Morisani, the operation he has revived in preference to it (*i.e.*, craniotomy), has no greater fatality, and possesses the material advantage of saving the fœtus. In these days, when the opposition to craniotomy increases as the risks of the Cæsarean section diminish, there is a growing inclination on the part of gynecologists to adopt the use of the knife, in some one of the several forms in which it may be employed, for the saving of mother and child. The Sänger operation is now the most highly extolled for its moderate death-rate, and fœtal-saving under it is almost universal. But there is an objection of long standing against the Cæsarean section, where the sacro-pubic diameter measures from two and three-fourths to three and one-fourth inches. A well developed fœtus will become head-locked in a three-inch pelvis, and will die if not liberated; craniotomy may accomplish this, with very little risk to the woman, but the child will be lost. Fœtus after fœtus has been thus disposed of, for one and the same woman, until a numerous progeny has been destroyed that she might escape death. Should there not be an end to infantile destruction in such cases, and does not symphysiotomy afford a means whereby the fœtus may be saved, without very great danger to the mother?

The induction of premature labor, as in the hands of the late Dr. Cæsare Belleozzi, of Bologna, who operated more than one hundred and twelve times, may accomplish this end; but what is to be done where the patient is not examined until near her maturity of gestation, or in actual labor? There is this to be claimed in favor of symphysiotomy, or the Sänger Cæsarean operation at full term, that a very small proportion of infants delivered prematurely, live through the first year, because of their immaturity of development. *Robert P. Harris.*

SYNCOPE, or fainting, is a condition of sudden unconsciousness of short duration, ending with complete recovery. It can be produced by unpleasant mental impressions, such as fear, dread, and shocking news, or the sight of suffering of others. Some persons faint from the sight of blood or the expectation of any trivial operation. Acute personal suffering may also lead to syncope, perhaps more through mental influences than by direct reflex action. Operations on the ear and the male genital organs are especially apt to cause fainting. Oppressive heat may also induce fainting. While syncope may occur in perfect health, though rarely, it is much more likely to take place in conditions of enfeebled health. Nervousness, in the sense of imperfect control of the inhibitory nervous system, anæmia, convalescence from debilitating diseases, and almost all forms of heart disease, render the individual prone to fainting on slight provocations.

Prior to the loss of consciousness the subject feels weak and faint, sometimes dizzy, becomes pale in the face, which is usually covered with cold sweat; the sight fails, everything becomes dark, there is often a roaring noise in the ears, until at last the control over the muscles is lost and the subject falls down unconscious and limp.

The unconsciousness lasts rarely longer than a few minutes. On recovery a feeling of faintness may persist for a short time. In enfeebled health several fainting fits may follow in succession. On the other hand, the tendency to syncope may be checked before unconsciousness occurs by removing the cause—for instance, avoiding the sight of some awe-inspiring scene.

On account of the rapid and perfect recovery, a fainting fit could hardly be mistaken for an apoplectic seizure. From major epilepsy it differs by the want of spasms. But from an attack of minor epilepsy (petit mal) fainting cannot be distinguished, except by taking into account the preceding causes, if any, and the history.

In the light of modern physiological knowledge the essential condition of syncope must be regarded as anæmia of the brain, presumably the cerebral cortex—the seat of consciousness. For unconsciousness can be experimentally produced in animals by inducing cerebral anæmia, as by hæmorrhage or ligature of the carotid and vertebral arteries, and it occurs also in man under similar conditions. The pallor of the face during fainting renders it likely that the blood-vessels inside of the cranium are also constricted. Moreover, any measures which increase the blood-supply to the brain, like the recumbent position or the inhalation of nitrite of amyl, may check the fainting tendency before consciousness is lost. The cerebral anæmia produced in animals by hæmorrhage or ligature of the arteries of the head leads to convulsions, while in ordinary fainting no muscular spasms occur. Whether the anæmia during syncope is not as intense as during the experimental state, or whether the constriction of the blood-vessels does not involve the region of the basal ganglia in syncope, is not settled. The pulse is usually slow during fainting, and sometimes long pauses exist between separate pulsations—evidently action of the vagus. This inhibition of the heart through vagus action occurs similarly in experimental cerebral anæmia from excitation of the vagus centre. Whether a primary excitation of the vagus can lead to fainting is not known. In most instances fainting must be regarded as an influence of emotions upon the centres of the vaso-constrictor nerves of the cerebral hemispheres.

In order to prevent the loss of consciousness from a threatening attack of fainting the cause should be avoided as far as possible. It is well to loosen any tight apparel, especially the corsets of women, since constriction of the waist increases the liability to syncope. The cerebral anæmia should be counteracted by placing the patient on his back, with the head low. Unnecessary meddling is not called for. Amyl nitrite may be of service if on hand. These measures may also shorten the period of unconsciousness. For this purpose any mode of stimulation of the skin, like a fresh draught or sprinkling with cold water, may also be employed. The liability to fainting can be combated only by those means which restore a more or less perfect health according to the general condition of the patient.

H. Gradle.

SYNOVITIS, ACUTE. Synonyms: Hydrops articulorum acutus, acute serous synovitis, arthro-meningitis, sero-synovitis; French, Synovite aiguë; German, Die Synovitis.

Synovial membranes approach so closely to the serous membranes that they are often classified with them.

Anatomy.

But, although structurally much the same, they differ from the serous membranes in secreting a peculiar fluid, synovia, and they are not, like the peritoneum, etc., closed sacs. In all joints where motion takes place (diarthrodia) a lubricating fluid is necessary, and this fluid is furnished by the so-called synovial membrane, the structure and pathology of which we come now to consider. Every diarthrodial joint is lined with a layer of synovial membrane, except in the places where the articular cartilages are in contact. Here there is no membrane,[1] except at the edge of the cartilages, which the synovial membrane may overlap for two or three millimetres,[2] before merging into the cartilaginous structure. Fasciculi, and folds of the capsule, the internal ligaments, and fatty internal protrusions are all covered by the membrane. In the fœtus an endothelial layer is found over the cartilages, which wears off when the joints begin to be used. The limits of the synovial membrane are most easily made out in inflammation, when a red collarette is seen surrounding the white cartilages. Farabœuf[3] compares this to the chemosis in acute conjunctivitis.

Synovial membrane is thin and elastic. Externally it merges into the tissue of the joint-capsule, while its inner surface is smooth and moist. Histologically the structure is a basement tissue of elastic and connective-tissue fibres, upon the inner surface of which lies a single layer of endothelial cells (His). Hueter[4] has, however, asserted that there is no such pavement layer, but only clumps of cells here and there; but his methods of examination seem to have been at fault.[5] In gross the inner surface of a joint presents a smooth and shining surface, interrupted, especially where the membrane folds to pass from one surface to another, by the synovial fringes (plicæ synoviales)—villous structures of varying size and length, somewhat resembling intestinal villi, the largest being perhaps one centimetre long. These fringes were thought by Havers,[6] who described them, to be true glands, and he called them mucilaginous glands. Subsequent anatomists disputed this, but Rainey[7] found them in structure to be secreting organs. They are richly supplied with blood-vessels, for each villus contains the convoluted twig of an artery. Some of the fringes, however, are merely hernia-like protrusions into the joint of small masses of fat[3] covered by membrane; these fill up unoccupied spaces. The nerves are derived from the same nerve-trunks that supply the muscles of the limb. The nerve-filaments terminate in small plexuses, unequally distributed, under the synovial membrane. The lymphatic network is not easily demonstrated, but that it exists is evident from the fact that coloring matter injected into the joint disappears very quickly, to reappear in the lymphatic channels of the limb.

Synovia is a clear, alkaline fluid, much like the white of egg in general appearance; when rubbed between the fingers it imparts an oily sensation. It is largely secreted by the cells which cover the synovial fringes. In structure it contains albumen, mucin, some fat, leucocytes, and epithelial cells. A fluid identical in composition with synovia can be produced by rubbing up a portion of the epidermis in a weak alkaline solution. This fact suggests[8] that most of the mucin is derived from the endothelial cells soaking in the weak alkaline fluid secreted by the fringes, and this view is strengthened by the fact, discovered by Frerichs,[9] that, when joints are quiet, the synovia in them contains only half as much mucin as when they are in motion.

Pathology. The classification of acute inflammations of the synovial membranes is best made, on a simple pathological basis, according to the following scheme:

(1) Synovitis with effusion—serous, purulent.

(2) Synovitis without effusion, dry or plastic synovitis.

Acute serous synovitis is the most common of all. The pathological process is simple and typical; for some known or unknown cause, a joint, most frequently the knee, becomes the seat of an inflammation which is manifested in the usual way. There are hyperæmia of the vessels of the membrane, an increased rapidity of the blood-current, and then dilatation of the capillaries, with stasis. Migration of the white corpuscles from the vessels follows, and a profuse serous secretion is poured out from the dilated vessels into the perisynovial tissues and into the joint. The endothelial cells are very rapidly produced, and are cast off, half formed, into the joint. This process, carried far enough, constitutes "catarrhal synovitis," a purulent form. To the naked eye the surface of the membrane is seen to be bright red, from the dilatation of the surface capillaries; it is not so shiny as usual, and has ordinarily a boggy, softened, œdematous appearance, from infiltration, which is most noticeable in the synovial fringes. Here and there, especially in the more acute cases, may be seen a patch of extravasation, where a distended blood-vessel has burst. The fluid in the joint is often colored more or less red by these extravasations. The cartilages in an inflammation of this grade are not affected, but are seen to be of a clear bluish-white color, and surrounded by the sharply marked line of inflamed synovial membrane.

The joint at this stage is more or less distended with an abnormally large amount of synovial fluid, at first thinner than usual, on account of the copious effusion of serum into the joint, then becoming more or less opalescent as the endothelial cells are cast off into it and become macerated, and as the leucocytes increase in number. The amount of fibrin in the fluid varies greatly; in severe acute attacks the amount is generally so large that the fluid is glairy and sticky, and, on standing, distinct flocculi separate out and float around. When there is so much fibrin in the joint-fluid that it consolidates on the synovial surfaces, the case belongs rather to the class of dry synovitis. At this stage, unless it become chronic, the inflammation subsides, or goes on to the formation of a purulent exudation. If it subsides, the blood-supply diminishes, the newly formed capillaries are obliterated, and the distended ones resume their normal calibre, the cell-proliferation ceases, the cells already thrown off furnish mucin to the synovia, the excess of fluid is absorbed, and everything returns to a normal condition. The synovitis is cured.

If, however, instead of undergoing resolution, the joint-inflammation takes on a more active, perhaps a more destructive, character, we have soon to deal with a purulent effusion. Cell-proliferation and the migration of leucocytes become so prominent a part of the process, that where there was formerly serum there is now a sero-purulent or purulent fluid. From being simply red and glazed the synovial surface becomes velvety in appearance, and the cartilages become yellowish-white and their surface is indistinct and covered with lymph and flocculi of pus. In some cases the destructive process seems localized, and ulcerations of synovial tissue, and even of cartilage, take place, while the surrounding parts show only a moderate grade of inflammation. From this it is easy to see how any amount of mischief may result. The whole synovial membrane may become granulating tissue, the cartilage is perhaps eroded also, the bone is bare, and the periarticular tissues become the seat of abscesses as soon as the capsule breaks, perhaps before. It is hard to set a limit to so destructive a process as this. Two grades of this purulent effusion are properly recognized: One, called purulent synovitis, where the pus is secreted by the surface layers of the membrane and no deep-seated lesion results; this is the "catarrhal inflammation" of Volkmann,[10] and often appears to lack any serous stage. It is said to be rather "the perversion of an excessive secretion than an inflammatory tissue-degeneration." The second grade is called suppurative synovitis, and it signifies that the deeper layers of the membrane are involved.

Recovery from purulent synovitis may be complete, and no trace of the mischief may be left behind. Recovery from suppurative synovitis generally, although not necessarily, means a joint impaired by adhesions. On the other hand, as we have seen, there is no limit to the destructive possibilities of suppurative synovitis; complete disorganization of the joint, dislocation of the bones, and, worst of all, systemic infection are only too apt to follow.

Dry synovitis, arthro-meningitis crouposa, is a very obscure affection pathologically. There is an absence of much fluid, as the name implies, and the synovial membrane is covered with a dry, leathery coating, which appears to be the deposition from a slight exudation, very rich in fibrin, into the joint. Anchylosis of the joint may follow with surprising rapidity. This form of synovitis is much more common in the sheaths of tendons than in the joints. Hueter[11] believes that suppurative synovitis often results from this, and he prefers to call it synovitis sero-fibrinosa.

Symptoms. In few pathological conditions are the four classical symptoms of inflammation more marked than in acute synovitis. Pain, heat, redness, and swelling comprise a large part of all that can be said of it. First, in simple acute synovitis: A few hours after the receipt of a wound or blow, some wrench, some exposure, or over-exertion of a joint, commonly the knee, an uneasy, hot feeling is noticed, and before long it becomes a positive pain. This is associated with a tense, burning feeling and a sense of helplessness in the affected limb. Any motion adds to the discomfort, and manipulation of the joint, if carried to extreme flexion or extension, causes pain; sometimes any motion at all is painful. The feeling of distention that accompanies the height of the effusion may be distressing, but from the sixth, seventh, or eighth day, when this height is reached, the pain rapidly subsides. The pain is ordinarily felt in the joint that is inflamed, but it may be "reflected" to some other joint supplied by the same nerve-trunks. This curious phenomenon is most frequently noticed in hip-joint inflammation, where the pain may be referred to the knee of the affected side. The intimate relations and anastomoses of the sciatic, obturator, and anterior crural nerves seem to furnish the best explanation of this, although Bonnet thought it due to the position of the patient, lying in bed with the leg rolled over on its outer side, a consequent strain being put upon the external lateral ligaments. Wright says that there are three factors in this knee-pain: (1) The nerve-relations mentioned above; (2) sympathy between the ends of the bones; (3) muscular spasm. When the synovitis becomes purulent, or is so from the first, pain is a more prominent symptom and much more severe than it is in simple synovitis. If it goes on to destruction of the joint-structures and to osteitis, the pain becomes extreme, and the patient is waked from sleep at night by the muscular jerks (starting-pains), which press the inflamed and ulcerated joint-surfaces together. Even in simple synovitis the pain is worse at night.

Pain.

Tenderness. Along with the pain goes tenderness in most cases, as one would expect from the inflamed condition of the synovial sac and the irritable state of the articular nerves. Hyperæsthesia of the skin is especially present in pyæmic synovitis, but the ordinary tenderness is the pain felt on deep pressure and manipulation of the inflamed joint. There is a spot in each joint where tenderness is apt to be especially marked: In the knee it is over the inner condyle, about a finger's breadth inside of the inner border of the patella; in the ankle-joint, in front of the outer malleolus; in the hip, behind the great trochanter. The pain meantime is by no means localized, but there is a bruised, helpless feeling extending to the whole joint. Certain cases, however, are characterized by severe local pain and tenderness in some one spot, and these cases are considered by Volkmann[10] to be due to the deposit of a

fibrinous clot on the synovial membrane at that spot; the theory, however, lacks anatomical proof.

In simple serous synovitis intra-articular swelling begins on the first, second, third, or fourth day. It is of **Swelling.** two kinds—effusion into the joint and effusion around the joint. In simple synovitis the infiltration into the periarticular tissues is slight, but if pus appears the skin becomes red and boggy, and it is seen that serum has infiltrated into the tissues around the joint. The same is true of the periarticular infiltration associated with acute rheumatism, where the periarticular infiltration makes a shapeless and puffy joint; whereas intra-articular distention betrays itself by a characteristic shape in each superficial joint, dependent upon the elasticity of each synovial sac. This intra-articular distention varies from a small effusion up to a condition in which the skin is shiny, tense, and pale, and the venous return from the lower segment of the limb may be so much impeded that the superficial veins stand out as if ready to burst; or an exudation may take place from the obstructed and overfilled vessels and produce a most marked œdema of the foot and ankle. The capacity of the sac of the knee-joint, when extremely distended, is some six or seven ounces; in average cases of simple synovitis it holds about four ounces. The average capacity of the shoulder-joint sac is three ounces.[8] But in the deeper joints swelling may not be discoverable; in the hip, for instance, there may be no such signs of articular distention to be found, or the soft parts in front of the joint may be full and prominent, and sometimes fluctuation may be felt through the joint.[14] The common state of affairs in both hip- and shoulder-joints acutely inflamed is a general enlargement of the joint, without the clearly articular shape to be seen in the knee and elbow, for instance.

Redness and heat are less constant and less important symptoms than pain and swelling. Redness is not often present in simple synovitis, especially when **Redness and heat.** there is much effusion; in such case the skin is apt to be paler than normal, from the pressure upon the skin and superficial blood-vessels by the distended capsule. Pyæmic, gouty, or rheumatic synovitis is apt to be attended by a blush, which is generally quite marked in the two latter affections. In the case of the deeper joints redness as well as heat is ordinarily absent. More or less local heat about the inflamed joint is present. In an acute serous synovitis the rise of local temperature is, according to Barwell, from 1.5° to 2.4° F. above the normal. If the synovitis is purulent or suppurative, the local rise of heat is as great as in any acute purulent inflammation.

When in a state of acute inflammation a fairly constant abnormal position is assumed by each joint; the **Position.** semiflexion of the knee in knee-joint synovitis will serve well enough as a type. The hip is flexed and adducted or abducted, the ankle is slightly extended, the arm is carried at the side, the elbow is flexed at a right angle, and the wrist drops slightly and is somewhat flexed. Fixation of the muscles holding the joint is present at the same time, and the abnormal position is firmly maintained by them when manipulation of the joint is attempted. At first this muscular guard seems to be purely voluntary, and is only excited by the pain which movement causes, but in time it becomes involuntary, until in chronic joint disease it may be present in cases where movement causes no pain at all. Bonnet, of Lyons,[12] investigated this question of malposition in inflammation, making some experiments which have become classical, and until lately his theory met with universal acceptance. Joints in the cadaver were injected with fluid by means of an ordinary hand syringe, and Bonnet found that the limbs assumed the same positions as when inflamed during life. Solidifying injections showed also that the joint-capsule possessed the greatest capacity in these positions. So here was afforded an easy solution of the whole problem—the limb simply assumed the position in which the joint would hold the most fluid. But certain objections were urged against this theory. Bonnet's injections had been made with so much pressure that the condition of affairs in the joint was not to be compared with that in acute synovitis. And there are two very forcible clinical objections—certain cases of knee-joint disease, for example, with an extreme amount of effusion, present little or no flexion, and in the whole class of chronic tuberculous joint diseases, where the malpositions are most marked and most constant, effusion is oftenest absent or very slight in amount.[15] All this, of course, points to some second factor in originating and maintaining these positions. The explanation of Hilton[16] represents the other point of view; he says "that the irritated or inflamed condition of the interior of the joint (say the knee-joint), involving the whole of the articular nerves, excites a corresponding condition of irritation in the same trunks which supply both sets of muscles, extensors, and flexors; but that the flexors, by virtue of their superior strength, compel the limb to obey them, and so force the joint into its flexed condition." This phase of the question is elaborated a little more fully by Lücke,[17] who says that the extensors are lighter in color, and are not so well supplied with blood,[19] and that impairment of motor functions, after fatigue from electrical stimulation, is more marked in the extensors than in the flexors.[18] In summing up, Lücke offers practically the same explanation that Hilton does, saying that the patient finds it most comfortable to hold the limb in this position, all the muscles being tense and set. It is easy to see that the whole question of the position of inflamed joints is far from settled.

Atrophy of the muscles controlling an inflamed joint begins early and may be very marked, even in a simple **Atrophy.** acute synovitis. In five cases, seen by Valtat[20] from the eighth to the eleventh day of the synovitis, muscular atrophy was present in all to the extent of at least two or three centimetres. The character of the joint disease seems to matter but little in the production of this phenomenon. Traumatic or simple, acute or chronic, serous or purulent synovitis, all show muscular atrophy, and the more acute the disease, the faster the wasting goes on. That this is something more than the mere atrophy of disuse is shown by the fact that it begins so sharply and so early, that it is greater in the diseased limb than in the well one, even when the patient has been in bed from the first, and that the muscles, although atrophied, are not soft and flabby, but tense. Sir James Paget says: "I wish I could explain it better than by calling it reflex atrophy," and Brown-Séquard's experiments lead him to think that the trouble is an irritation of the nerves, and independent of the trophic centres. Valtat injected the joints of guinea-pigs and dogs with irritant solutions, mustard-oil and ammonia, and found that muscular atrophy came on quickly. In one case, in eight days there had been a loss of thirty-two per cent. by weight in the anterior thigh-muscles, and twenty-four per cent. in the anterior calf-muscles; in another case it reached forty-four per cent., and in all cases the extensors wasted more rapidly than the flexors. He attributes much influence in the matter to the amount of pain present, a point already clinically noted by Paget. **Paralysis.** Valtat also calls attention, in this connection, to the paralysis of the muscles of the affected limb often accompanying acute joint disease, the loss of power already mentioned, and also a diminution of faradic excitability after severe muscular wasting. In a case of knee-joint synovitis, which he mentions, there was complete paralysis of the flexors of the leg at the end of twenty-four hours. Such a paralysis, to a greater or less degree, seems to precede the wasting of the muscles.

The general condition of a patient with simple acute synovitis suffers but little. The rise of temperature, if **General condition.** any, is slight, unless a rheumatic condition exists, and only with the advent of pus does the temperature rise to any extent. A sudden chill, an increase of pain, a tendency to fever, all make one suspect the formation of pus, and when that has once come the general condition may become ever so bad. Gonorrhœal, rheumatic, and pyæmic synovitis are accompanied by fever and the other symptoms of the affections which they represent.

It is hardly worth while to go deeply into the symptomatology of dry synovitis. It is rare, and its clinical as well as its pathological characteristics are but ill defined. Bonnet describes it as being characterized by much fever and periarticular swelling, severe pain, with a tendency to bad positions, and rapid obliteration of the joint by anchylosis. Barwell says that the pain of synovitis with effusion is not worthy of comparison as to severity with the pain of dry synovitis, and that there is always pyrexia and a doughy look to the skin, and he, too, speaks of the tendency to anchylosis. Volkmann thinks that Bonnet confused this affection with ulceration of the cartilages. However, the fact remains that there are cases of joint disease in which pain, and not swelling, is the prominent symptom, where no pus can be found, and where anchylosis is most rapid and unexpected.

Varieties.

Considered in relation to cause, acute synovitis falls into two classes, traumatic and non-traumatic, as shown in the following schema:

Synovitis acute.
- Traumatic.
- Non-traumatic.
  - Simple,
    - From exposure,
    - From over-exertion.
    - Not to be accounted for.
  - Rheumatic,
  - Gonorrhœal,
  - Pyæmic,
  - Puerperal,
  - Exanthematous,
  - Gouty,
  - Syphilitic,
  - Secondary to neighboring disease,
  - Catamenial and metric.

Traumatic synovitis is, of course, the more common, since sprains, blows, and wounds of all sorts are likely to contribute more cases than all the rest put together (see Joints, Injuries to). The non-traumatic forms of synovitis chiefly claim our consideration here. Laying aside, then, traumatism, the most frequent causes of simple serous synovitis are exposure to cold or wet and overuse of the limb affected, and consequent direct mechanical irritation of the joint. This is often enough called rheumatic, even when it lacks the constitutional symptoms of acute rheumatism, and occurs in persons by no means predisposed to rheumatic attacks. Such cases may be rheumatic, yet they lack evidence of being so, and the term had much better be reserved for the form of synovitis, generally polyarticular, which accompanies the attacks of more or less generalized rheumatism.

Simple synovitis sometimes arises when it is impossible to assign any cause for it, and pursues its regular course; this form, too, is called rheumatic, on evidence which may be very good or very insufficient. Acute simple synovitis occurs mostly in young adults, and is more frequent in men than in women.

What should really be called rheumatic synovitis is only too familiar in acute articular rheumatism. It is serous in character, and the extra-articular swelling is apt to predominate and mask the distention of the synovial sac. It may involve one or, more commonly, several joints, and is, of course, associated with the constitutional symptoms of rheumatism; ordinarily it is a simple serous synovitis, lasting from three days to several weeks; it rarely goes on to suppuration, and it shows a strong tendency to become subacute or chronic.

Gonorrhœal or urethral synovitis stands half-way between the rheumatic and pyæmic varieties, and possesses some features of each. It occurs oftenest in the second week of an acute urethritis, and ordinarily attacks the knee, but no joint is exempt. It generally attacks one joint at a time, but it may be polyarticular. It may come on acutely, with fever and much pain, or it may begin insidiously and pursue a more chronic course. It is occasionally found in women, but is very much more rare in them than in men.[23] The manner of its relation to gonorrhœa is not known; the doctrine that it was a metastasis is no longer held, nor does the suggestion that it is due to a mild purulent infection meet with much acceptance. It may even follow the passage of a sound, or some urethral irritation where no gonorrhœa exists;[24] ordinarily it is serous, and is stubborn and painful; sometimes, though rarely, it becomes suppurative, and simulates pyæmic synovitis very closely.

Pyæmic synovitis is characterized by the rapid formation of pus in a joint, ordinarily the knee, ankle, or shoulder; and the inflammation of this joint is apt to be followed by that of several others, involved in rapid succession. The serous stage is generally unnoted, although it is probably present. Associated as this affection is with general pyæmia, there is little to be expected that is favorable. The destruction is generally rapid and extensive, and the pus which is evacuated may be thin and foul, or thick and flaky. Formerly a separate class was made of puerperal synovitis; but since the nature of puerperal fever has been recognized, this form naturally falls under the class pyæmic, where its symptoms entitle it to a place. It is apt to be milder, however, than ordinary pyæmic synovitis. A class of pyæmic joint-affections in new-born children, resulting from infection from a suppurating cord, has been described by Mildner.[25]

Cases of synovitis sometimes follow the exanthemata and typhoid fever. Of the exanthems, not even varicella is always exempt, but scarlatina and measles are most likely to leave joint-complications. The synovitis ordinarily comes on during convalescence, and the frequency with which chronic tubercular osteitis is found after the exanthemata[26] suggests the possibility of the transition of the acute synovitis into this affection; ordinarily it is a serous synovitis, almost always polyarticular, and although it usually simulates rheumatic synovitis and is mild, it may become suppurative and follow more closely the course of the pyæmic affection. Fortunately, inflammations of this class are rather rare; an idea of its frequency in typhoid fever may be obtained from the statistics of Güterbock,[27] derived from 3,130 cases treated at the Vienna Hospital from 1868–71, where only 2 cases of joint-complication were noted. And Barwell could find no joint-complications on record in the London Fever Hospital.

Gouty synovitis is the local manifestation of the general disease. It is a serous synovitis, ordinarily of the great-toe joint, with considerable periarticular infiltration and redness of the skin. It tends to involve other joints in succession, and there is at the same time going on a slow change in the joint—alteration of the cartilages, and a deposit of urate of soda in them—and finally erosion of the cartilages down to the bone, with obliteration of the joint. In short, there is a chronic structural change in the joint, which is merely interrupted by these attacks of acute synovitis.

The occasional occurrence of clearly marked acute synovitis, either monarticular in the knee, or polyarticular, is noted in the febrile stage of syphilis.[28]

There is a class of cases of acute purulent synovitis which can be best designated as synovitis from direct infection. Such cases occur in acute periosteitis, acute osteomyelitis, chronic osteitis, and periarticular abscess, in all of which the disease is apt to be located near the ends of the bones. In periosteitis the pus collecting under the periosteum may break through and escape externally, or burrow along to the joint and enter it. In the latter case, of course, an acute purulent inflammation of the joint immediately starts up. Osteo-myelitis, in its destructive course, is likely enough to reach a joint and the pus to enter it, when the same purulent infection will occur. In chronic osteitis of even slight extent a tubercular nodule may have formed in the epiphysis near the joint-surface; it softens and breaks down, and, instead of passing into the outside tissues, the pus follows the line of least resistance and reaches the joint by perforation of the cartilage. The chronic symptoms light up with a fresh accession and an acute synovitis is clearly present. There seems, also, reason to believe that an acute synovitis may be secondary to a chronic abscess, probably tubercular in character, which in its course reaches and enters the joint-capsule. These last four classes of cases are, of course, merely secondary and incidental to a chronic and much more important disease, but they deserve mention.

Under miscellaneous cases should be mentioned what Barwell calls catamenial and metric synovitis, a multiple synovitis which he considers analogous to the urethral synovitis of men. It occurs (1) in pregnant women; (2) a month to six weeks after labor in women who have not had puerperal fever; (3) in non-pregnant women in connection with menstrual irregularity or suppression. Mr. Thomas Smith calls attention to a peculiarly destructive form of synovitis in infants, which he calls "acute suppurative arthritis." It ordinarily begins from the synovial cavity, but not always, and its origin is neither traumatic nor syphilitic.

Diagnosis.

First, as to the diagnosis of synovitis with effusion: The swelling produced by the distended capsule is the most characteristic sign; it is irregular in outline, bulging, and fluctuating, where the joint is superficial. In the ankle-joint the swelling is not very clearly marked, but it ordinarily is chiefly anterior and the capsule bulges out in front of the malleoli. In the knee the patella is lifted by the effusion, and floats. In examination for this the fingers of both hands should encircle the limb firmly in front, above and below the patella, thus confining the effusion to the space directly under the patella and over the intercondyloid depression on the femur. The forefinger of one hand then lightly but sharply presses on the patella, which can be felt to descend and hit the femur. This matter of fully extending the leg and grasping it is of much importance, as otherwise a small effusion may escape detection. Acute synovitis of the hip is a rather obscure affection, and in children the diagnosis is not generally possible. In cases with much effusion in adults, however, swelling may be found in the groin above Poupart's ligament and behind the great trochanter. In the case of the shoulder the whole joint is larger than usual, without any definite outline; and if the distention is great, the axilla may be more shallow than normally, and the depression beneath the acromion behind is lost. In the elbow there is bulging of the sac behind on each side of the triceps tendon. The wrist, when inflamed, shows an encircling swelling. The positions assumed by the various joints, when inflamed, have been given above, but simple position is of little service in differentiating synovitis from other joint- and bone-affections, and the same is true of muscular atrophy. Synovitis is to be distinguished from osteitis, bursitis, articular neuralgia, and hysterical joint disease. A diagnosis of acute synovitis in children should be made with very great care, for they are not prone to have acute synovitis, and are very prone to have chronic osteitis. The diagnosis, for example, between acute synovitis of the hip and morbus coxarius can ordinarily be made in the case of adults, but in children the diagnosis of an acute synovial inflammation of the hip should be made only after permanent recovery has followed, in a few weeks, upon the symptoms caused by an injury, not at the time of the acute symptoms. Let anyone read the symptoms of acute hip synovitis, as Gibney,[26] *e.g.*, gives them, and see which of them, except speedy recovery, is not compatible with hip disease. Suppose that a tubercular focus has been formed in the epiphysis of the femur near the joint, when the pus reaches the joint, just as likely as not after some fall, of course an acute synovitis is set up, as we have seen. That may be the first symptom in the case,[30] and if a diagnosis of primary acute synovitis is made, as the symptoms would seem to warrant, it is a serious blunder. The same is true of all the joints, when children are to be considered. There are cases of primary acute synovitis in children; they are not common, to be sure, but no attempt is made to deny their existence; simply the practical diagnosis cannot ordinarily be made. Typical bone disease begins with stiffness of the joint, pain—especially at night, interrupting sleep—wasting of the muscles of the limb, and absence of effusion. With regard to the chief diagnostic mark of typical synovitis I quote from Mr. Bryant: "Any inflammation of the synovial membrane, of whatever kind, always shows itself within a few days or hours of its origin, by effusion and consequent distention of the articulation."

From bursitis, synovitis is distinguished by the different location of the swelling, the less degree of joint-stiffness and pain, except when manipulation bears directly on the inflamed bursa, and the absence of muscular atrophy. In the case of deep bursæ the differential diagnosis may not be easy at first. Bursitis, however, rarely begins without cause; it is associated oftenest with mechanical irritation, as the names "housemaid's knee," "miner's elbow," etc., show. It should be remembered, however, that bursæ often communicate with joints, and that synovitis and bursitis may exist together during an acute synovial inflammation. The bursæ, when inflamed, form in their way as characteristic a swelling in each joint as the joint-capsule itself, when distended by intra-articular effusion. The two are easily distinguished. Articular neuralgia is said to exist apart from joint disease.[32] The pain is out of proportion to the local symptoms, heat and swelling are not present, cutaneous hyperæsthesia generally is, and so, possibly, is muscular fixation.

Hysteria simulates chronic oftener than acute joint disease, yet sometimes, following a fall or an over-exertion, sensations closely simulating the symptoms of an acute synovitis may be complained of. Ordinarily the diagnosis is easily enough made by the absence of heat, swelling, and localized tenderness, and by the general make-up of the patient, but some cases offer much difficulty, as muscular wasting and rigidity may be present to a marked degree.[33] Pyæmic, gouty, and rheumatic synovitis are easily to be distinguished from each other by the presence of the constitutional affections of which they are merely the symptoms, while urethral synovitis often offers some little trouble from the fact that the patient is anxious to conceal his urethral discharge. Rheumatoid arthritis belongs rather to the class of chronic joint diseases, and would hardly be confounded with acute synovitis.

Finally, as to the diagnosis of dry synovitis: Its acuteness, severe pain, and the absence of swelling are its leading characteristics. To diagnosticate it from osteitis would be sometimes impossible, but ordinarily its more acute course will establish its identity. From the other affections it can be more easily distinguished by the methods mentioned in the section on the diagnosis of synovitis with effusion.

Prognosis.

The prognosis in simple serous synovitis of traumatic or non-traumatic origin in adults is good, if the general condition of the individual affected be even fair. Suppuration is not common, except from wounds; and when it occurs, there is generally some evident cause for it, such as infection by tapping, a broken-down constitution, etc. Under effective treatment a complete restoration of the joint is the rule. From the sixth to the eighth day the effusion will ordinarily begin to subside, and its absorption is much aided by pressure and rest. The third possibility in a simple synovitis is that it may become chronic. In some cases the swelling does not subside much, but the pain goes away, and, although the joint remains swollen, the patient may go to business and use the leg fairly, but he has dropsy of the joint, chronic serous synovitis, or an irritability may remain after the absorption of the fluid, and succeeding light attacks may follow one another, each leaving the joint worse than it was before; these cases are apt to eventuate in chronic joint disease. Neither of these latter classes is very common in healthy adults, and the prognosis is, as we have seen, favorable, especially when, after the appearance of the effusion, the pain and fever quickly subside. Rheumatic synovitis, on the other hand, has a tendency to become subacute or chronic, and to leave stiff joints. The occurrence of suppuration in either rheumatic or simple synovitis is a serious matter, and, although prompt treatment will in most cases be efficient, the prognosis will be much more doubtful, especially if the suppuration should have come on without apparent cause. The occurrence of a joint-affection in pyæmia does not make very much difference in the outlook, for the prognosis depends wholly upon the general character of the disease, whether mild or malignant. If mild, in from

five to ten days the joint-symptoms improve, and a complete restoration of the joint is not impossible.[34] On the other hand, the destruction may go on to any extent, preceding a fatal termination. In general, however, it is not common to find complete restoration of joint-function after either purulent or suppurative synovitis, although it may take place. The synovitis occurring after the exanthemata is said to tend toward recovery after a few days. At the same time, bearing in mind how often chronic joint disease follows these exanthemata,[35] it is best not to give an unreservedly favorable prognosis. The form occurring in typhoid fever is generally purulent and more grave. Gouty synovitis, when left alone, lasts from a week to ten days; efficient treatment will generally shorten its course to three or four days. Gonorrhœal synovitis is at best a slow affair; it is characterized by a slow course, with a tendency to relapse and become chronic. Recovery is not common in a less time than a month or six weeks.

The occurrence of synovitis as a complication in chronic osteitis is merely an incident in the course of a long disease.

Treatment. The important points in the treatment of acute synovitis are to put the joint at rest and to keep it so, and, secondly, to put it at rest in good position, so that if anchylosis should take place, as useful a limb as possible would be obtained; that is, the knee should be put up very slightly flexed, the elbow at a right angle, with the thumb upward, the hip very slightly flexed on the trunk and neither adducted nor abducted, the ankle at a right angle, the wrist in the line of the arm, and the shoulder with the arm at the side. The splint that offers the most definite and absolute support to the two limb-segments is to be chosen. Ordinary wood and tin splints, accurately padded and firmly applied, are generally the most serviceable, except in the ankle, where in severe cases carved wooden side splints often will not answer, and wet millboard or plaster of Paris must be applied; and in the hip, where bed-extension and a long outside splint, as in fractured thigh, will be most serviceable. Millboard splints are applied according to the directions of Gamgee.[36] The joint is wound by rollers of sheet-wadding until one or two layers cover it everywhere, then wet millboard is shaped to the joint and bandaged on by linen rollers, applied with firm, even compression, which may be considerable if the method is properly applied. Plaster of Paris splints are made by the application of crinoline-gauze bandages impregnated with finely divided plaster. The limb is first wound in sheet-wadding, and then the plaster rollers are applied. The method does not give in all cases certain, definite support. I quote from Dr. Judson[37] in regard to it. He says: "It may be an exaggeration, but it conveys the idea, to say that a plaster of Paris or silicate splint, applied to the leg and thigh, contains a mass of jelly in which the femur is but little restrained from motion."

The problem of getting a limb into good position for the application of a splint is not always an easy one. The knee, for example, is apt to be more flexed than is desirable, especially in a case of some days' duration; and if easy manipulation fails to bring it into correct position, recourse must be had to manipulation under ether, or extension by weight and pulley, before a ham-splint can be applied. Unless there is some strong reason to the contrary, the latter of the two methods should be chosen, and the muscles which maintain the flexion of the joint will be found to yield with surprising readiness to continuous extension, with even so small a weight as three to five pounds, counter-extension being obtained in the usual way, by raising the foot of the bed. Once obtained, this good position is easily kept. This extension method also relieves the pain and discomfort surprisingly in severe cases, whereas manipulation under ether is ordinarily so painful that opiates are required after it. It is not generally practicable to apply extension to the wrist or ankle. The plan of putting up the limb in whatever position it happens to be, and waiting for it to straighten under rest, is neither safe nor always effectual. With the larger joints rest in bed should be enforced. This treatment should be the same, whatever the origin or the character of the synovitis, with the one exception of that following penetrating wounds of the joints. Here cleanliness takes precedence of everything. If the opening is not already large enough through which to wash out the joint, it should be made so, and the whole joint thoroughly irrigated with 1 to 5,000 corrosive sublimate solution, or 1 to 30 carbolic acid; no means should be neglected to remove all foreign material from the joint, then the case should be dressed antiseptically and treated in the usual way.

Having then put the limb into good position, and having fixed it so, less important matters are to be considered. A simple synovitis of moderate severity may practically be let alone, after applying some compression to the distended sac. A flannel bandage, cut bias, to give the full elasticity of the cloth, affords light compression; small dried sponges, laid over the joint and held in place by stout linen rollers, and then wet, afford either the lightest or the most severe compression. The application of a rubber bandage is one of the most common forms of producing compression. It can be loosely applied and produce but light pressure, or by stretching it only slightly during its application very severe compression may be obtained. The objections to it are the macerating of the skin under it, and the tendency thereby induced to erythema and eczema, and also the fact that it must be very lightly applied, for with much tension the discomfort is likely to become unbearable a short time after application; but when properly used it is often of the greatest benefit. The method of Gamgee, above alluded to,[36] is applicable to almost any joint, and affords even, comfortable, and efficient compression. If, however, the intra-articular distention is extreme, or if at the end of a week it does not begin to diminish, the joint should be aspirated and compression at once applied. Dr. H. A. Martin said:[38] "I have never known a case where a joint was 'aspirated,' and no such support [as the rubber bandage] afterward applied, in which the effusion *did not return*, whether the synovitis was the result of injury or disease." If the aspiration is done with proper antiseptic precautions it is attended by practically no risk; simply a needle of fair size is thrust into the most elevated part of the sac and connected with a common aspirator-tube. The puncture should be sealed with plaster or iodoform collodion. The claims of Dr. Martin[39] for this method are clearly extravagant. I quote directly from his article: "(1) That in a little over nine years I have treated over one hundred and forty cases of synovitis of the knee and its sequelæ by aspiration, with a single strapping of the joint and subsequent use of the bandage. . . . (3) The patient was in nearly all cases permitted to walk about. (4) That in not a single instance had there been a failure of absolute and entire cure. (5) That in no instance had this desirable end been postponed for more than seventeen weeks," etc. The experience of other surgeons in this treatment does not coincide with that of Dr. Martin.

The application of cold to the joint often gives relief to the pain and a sense of comfort. This can be done by a poultice of ice and saw-dust, by the ice-bag, or by the rubber coil wound around the limb. In other cases warm applications are more agreeable and equally useful. Hot-water bags can be used, or poultices, or fomentations of laudanum and hot water. In any synovitis of a severe character in a full-blooded individual the application of leeches to the joint is a measure of the greatest value, especially if there is much local heat and tenderness, and a tendency to suppuration is suspected. Nor should the leeches be used sparingly; from six to twelve should be put on all over the joint, and allowed to fill themselves, and then the bleeding is either to be encouraged by warm applications or checked by cold ones, as seems most advisable. On the other hand, painting with iodine, blistering, firing, and the other forms of counter-irritation seem a needless and bothersome infliction in simple acute synovitis; if, however, it shows a tendency to become chronic, then the time for counter-irritation has come, and blisters encircling the joint, in connection with as-

piration and subsequent compression, should be made use of. When the effusion has subsided and only a moderate thickening of the tissues is left, the splint should be removed and passive motion begun at the earliest possible moment, along with massage; for the tendency which inflamed joints have to become anchylosed should always be borne in mind. The experiments of Moll[40] did but little to clear up this question of anchylosis; for although from them it was perfectly evident that a sound joint might be immobilized indefinitely without losing any of its mobility, yet when inflammation of the joint was present, from a fracture near it, Moll was unable to say in what proportion of cases anchylosis occurred, although the joint was obliterated in several of the animals experimented on. As to methods of manipulation and massage,[41] a skilled masseur is, of course, the best person to handle the limb, but deep kneading of the muscles and gentle flexion and extension of the joint, increasing in extent each day, answer every purpose. The muscular atrophy will cause the limb to be weak; and, if it has been severe, although it would probably recover itself, restoration can be hastened by the use of a weak continuous current, perhaps of the faradic also.[20] It is not worth while to attempt to use the limb very much until its function is fairly well restored by passive motion. The use of palm-oil, etc., is, of course, much inferior to massage with the dry hand, but if the pain persists, on using the limb, stimulating liniments and blisters are very useful. If anchylosis should have already taken place, there are two methods to pursue: (1) To break it up at once under ether, a method which will ordinarily cause a relapse of the synovitis; or (2) to wait some months before attacking it. The latter method will generally be advisable. The constitutional treatment of acute serous synovitis amounts to nothing more than the routine of keeping the bowels open, and administering diaphoretics if the temperature is elevated. If, however, there is any reason to suspect a rheumatic cause for the attack, salicylate of soda should be given in full doses.

When the formation of pus in a joint is once established, there is ordinarily only one treatment to be considered, namely, incision. When the skin over the joint becomes red and œdematous, and the pain more severe, and when the patient is feverish, a full purge should be given, the joint should be kept absolutely quiet, and leeches applied in abundance, followed by cold and light compression. If, now, the trouble increases and fluctuation is apparent, the introduction of an aspirating-needle will show pus in all probability, but aspiration will rarely give more than temporary relief. The joint must be opened by a free incision, made under every antiseptic precaution, thoroughly scrubbed out with corrosive sublimate or carbolic acid solutions, freely drained, and put into a desirable and fixed position, covered by a full antiseptic dressing. When the wound heals, passive motion should be begun at the earliest possible moment, in order to save as much of the joint's motion as possible. The constitutional condition of patients with purulent synovitis is not good, and should be treated by alcohol, quinine, iron, and forced nourishment. The treatment of rheumatic, gouty, and gonorrhœal synovitis is considered in the articles, elsewhere, treating of those affections. Joints affected with pyæmic synovitis must be opened, but antiseptic precautions are, of course, useless. The treatment of exanthematous synovitis should be especially watchful, and the patient's general condition should be most carefully looked after. *Robert W. Lovett.*

SYPHILIS. The word syphilis was probably first suggested by *Syphilus*, the name of one of the characters in a pastoral poem composed by Fracastor in 1530. This name was unquestionably coined by the poet for his fictitious character, by a combination of σῦς, hog, and φίλος, fond of—a not uncomplimentary designation for a swine-herd.

Definition.—Syphilis is a specific, infectious, and chronic disorder, resulting either from inheritance or from immediate or mediate transference of the disease from an infected to a sound individual, beginning always, in the latter event, after the lapse of a characteristic incubative period, by the appearance of an initial lesion, at the site of infection, commonly termed a chancre; and followed after an interval of time by symptoms of systemic derangement, usually evolved in a determinate order, which eventually may affect any organ of the body, one attack usually conferring upon the subject of the disease immunity against subsequent infection.

Synonyms.—Many of the names which have been employed to designate the disease seem to have originated in attempts to shift the reproach of its origin and existence from the people of one nation to those of another. It has been called morbus gallicus, the French disease, lues venerea, mal vénérien, vérole (in France), sifilide (in Italy), French pox, chronic pox, "bad disorder," "bad disease," Lustseuche, Krankheit der Französen, radezyge (in Sweden), and other names. It is also said to be identical with frambœsia and yaws, but there is some doubt as to these points.

History.—Toward the close of the fifteenth century, soon after, in fact, the discovery of a new continent, syphilis made its appearance among Europeans and became the subject of discussion in medical literature. By many it was then supposed to have originated in consequence of the relations newly established between the inhabitants of the old and of the new worlds, and it was therefore often termed the "American disease." Later investigation, however, makes it appear probable that syphilis appeared among the races of men at a more remote period of antiquity. Evidence of syphilitic disease of the bones has been recognized in the skeletons of prehistoric man.

In later and historic epochs also, symptoms scarcely to be distinguished in their description from those of syphilis are described in the ancient literatures of China, Mexico, Peru, Arabia, Greece, Rome, and in the sacred writings of the Hebrews. It is probable that, at the periods which have been assigned for the origin of the disease in the fifteenth century, its rapid extension was largely due to the awakened activities of mankind in the direction of geographical discovery and international traffic. It is a well-known fact that epidemics of infectious diseases are usually most severe in communities which have long been virgin of such accidents.

The literature of syphilis may almost be said to date from the period so long assigned as that of its first appear-

ance among the races of men. It has since been adorned by the names of such eminent medical authors as Astruc, Van Swieten, Boerhaave, Bell, Sydenham, Colles, Hunter, Ricord, Gross, and Bumstead. The contributions to the subject made by contemporary authors have been as voluminous as valuable. The evolution and involution of the syphilitic process in every organ and tissue of the body have been observed and described with as much detail and accuracy as have been bestowed upon any of the problems in medicine.

Geographical Distribution.—Syphilis exists to-day in almost every country to which commerce has pushed its ventures. The degree of its depredations in any province may be wellnigh regarded as a measure of the extent of the intercourse of the inhabitants of such a country with the world at large. It exists in Great Britain, Russia, France, Italy, Norway, Sweden, Denmark, Prussia, Austria, Portugal, Switzerland, and in every other country of Europe. Its victims are usually more numerous in the larger centres of population where the activities of trade are greatest. England, for example, with her enormous maritime traffic, pays a heavier price of this character for her commercial profits than France, which is popularly supposed to suffer in larger measure. In a few of these countries, Italy, for example, where many of the people are densely ignorant, filthy, and poor, epidemics of the disease have occurred with disastrous results. On the African coasts, in Egypt, Madagascar, and Abyssinia; in all countries of Asia with which Europeans sustain commercial relations; in Japan, where the disease is reported to be both widely prevalent and virulent; in the Levant; in all parts of Asia Minor, and throughout all districts lying upon the shores of the Black Sea, syphilis is found, varying both in types of intensity and in preponderance. The same is true of all the countries of North and South America, Oceanica, and the Sandwich Islands. In the United States of America, syphilis may be recognized in every hospital and in the practice of almost every physician of repute. It is fortunately, however, much more common in the large cities, the rural populations escaping to a happy extent. It is found here among those who are native to the soil, including the negroes and Indians, as well as among the Chinese and other individuals of foreign birth who have immigrated hither.

It appears, in brief, that the extent and severity of the disease are not related to climate, isothermal lines, or degrees of latitude and longitude. They are intimately related, rather, to certain social traits in mankind, distinguished in their commercial, military, and religious excursions, trading ventures, pilgrimages, wars, fairs (*e.g.*, that of Nijni-Novgorod), and encampments of armies; their hygienic and medicinal methods; and, more or less in consequence of what precedes, to the density of population and the degree of intelligence possessed by infected classes as displayed in their management of the malady.

Nature of the Disease.—Syphilis is a specific infectious disease, always occurring in consequence of transmission from a diseased to a sound individual, and always transmitted as such. It does not sustain etiological relations with scrofulosis, tuberculosis, leprosy, or any other known disorder. It is capable of transmission by inheritance, and also by the medium of fluids furnished by the pathological tissues of diseased individuals. These fluids when isolated may be said to embody all the power and potency of the disease, and hence are described as virulent, or containing the virus of syphilis.

This virus, or contagious element of the secretion, which may be removed from one individual and artificially introduced into another with the result of thus producing the complete evolution of the symptoms of the disease, has been the theme of much discussion. Its very existence has been doubted by Bru, Jourdan, and others. Chemical analysis has failed to isolate it. Salisbury, Lostorfer, and others, have thought they discovered the germs of the disease in this secretion, but failed to make good their pretensions. Later, Pisarevski, Klebs, Bermann, Aufrecht, Morison, and Birsch-Hirschfeld, have discovered, in fluids of this kind, micrococci, which by them were supposed to be the etiological factors of the disease. Finally, on November 12, 1884, Lustgarten announced to the Vienna Society of Medicine that he had recognized the bacilli of syphilis. They were somewhat smaller than those of tuberculosis, from two to seven thousandths of a millimetre in length, and about three thousandths of a millimetre in width, straight or curved, and isolated or grouped, with contents distinguishable in the form of from two to four light, ovoid, colorless points supposed to be spores. While Doutrelepont, Klemperer, and others have verified these observations, it is held by Cornil that the microbe, supposed by Lustgarten to be the essential element of the syphilitic virus, was indistinguishable in more than one-third of all chancres examined by him and his collaborators; while Koebner asserts that, though these organisms are recognized in most of the genital lesions of syphilis, they are not found in buccal and other extra-genital lesions of the same disease. The claim is also put forward that they are more or less identical with the bacilli which can be recognized in normal smegma. Lastly, it is admitted that the essential conditions requisite to establish the fact that any micro-organism is the sole factor in syphilis have never been satisfactorily met. These are: The fairly constant demonstration of the bacilli in lesions of syphilis, whether occurring in one or another region or viscus of the body; next, the reproduction of generations of these germs in sterilized culture-fluids; lastly, the infection of sound human beings by the medium of the latter, and the production in such infected subjects of a typical syphilis, capable of transmission to a sound individual by the usual methods.

In the absence of positive data of this kind, we are not, however, left for an explanation of the nature of syphilis to such mazes of speculation as were the only resource of the earlier writers on this subject. Though unable to declare to-day that this or that specific germ is the essential factor in the disease, the remarkable advance of knowledge on the subject of bacterial affections gives us a basis sufficient to establish the belief that syphilis belongs to the class of infectious granulomata; and is the result of the introduction of a parasite into the human economy. The disease should be classed to-day with tuberculosis and leprosy, whose etiological bases are now scarcely questioned; and, possibly, also with glanders, mycosis fungoides, actinomycosis, and other affections with respect to whose precise bacterial relations there is some doubt.

Neisser, in fully accepting the consequences that follow the acceptance of this position, established by analogy but unsupported by demonstrable fact, has in this light satisfactorily explained many of the phenomena of syphilis. The bacteria may be transmitted by intra-uterine inheritance or extra-uterine infection at a given point where multiplication of the germs occurs. Whether instantaneous general infection follows by the sudden admission of these micro-organisms into the circulating fluid; or by the slower process of invasion of the lymph-channels and extension through the lymph-glands to the general economy, it seems clear that the initial sclerosis of the disease, a "chancre," becomes a focus of infection which only gradually participates in the same process of distributing the germs of the disease throughout the general economy. Later, the lodgement of these germs in various parts of the body determines the development there of the specific products of the disease; possibly also exercises there that specific local modification which renders the tissue then capable of reacting in a certain characteristic morbid behavior, after the operation of external irritants (mucous patches in the mouth of the smoker, etc.). Neisser believes that the nearer the date of infection, the larger the number of bacteria present at any one moment in the body; and, as a corollary from the above, the more numerous, symmetrical, and superficial the lesions. But in later periods, with a smaller number of bacteria and a gradual decrease in capacity for infection and hereditary transmissibility, there are fewer, deeper, more asymmetrically disposed, and more malignant manifestations of the disease.

Evolution of the Disease in Periods.—Every case of acquired, as distinguished from inherited, syphilis begins with a chancre. Cases reported to have originated in other ways are to be regarded as instances of unrecognized chancre. In popular phraseology, the period of the disease during which are displayed the local phenomena of the chancre and its characteristic adenopathy of contiguous lymphatic glands is termed the period of primary syphilis. The period of so-called secondary syphilis is that which begins with the earliest symptoms of constitutional, as distinguished from purely local disease, and whose symptoms are, for the most part, as regards cutaneous manifestations, both symmetrical and superficial. Not only the skin and its appendages (nails, hair, etc.), but the eyes, lymphatic glands, and other organs may be affected in this period of the disease. It rarely begins as early as the twenty-fifth day after the appearance of the chancre; and is even more rarely postponed to the sixth month after such appearance. No definite term of duration can be assigned to its manifestations; hence the limit between so-called secondary and tertiary syphilis is of artificial importance and of variable date. Secondary manifestations in syphilis usually cease to occur after the second year of infection, but may be displayed for a year or more afterward.

So-called tertiary syphilis includes the later lesions of the disease, graver in type, deeper, often visceral in situation, and possibly single, usually asymmetrical in development. They may be evolved as early as the third or fourth month following the primary lesion, and persist or recur during a series of subsequent years. In exceptional cases there is a reversal of the order of evolution indicated by these popular phrases, first employed with precision by Ricord, so that so-called secondary syphilitic symptoms succeed the so-called tertiary. In tertiary syphilis the subcutaneous, osseous, fibrous, nervous, and other tissues of the body are affected, together with the viscera.

For a study of the symptoms displayed in the period of primary syphilis, the reader is referred to the admirable and complete article, entitled Chancre, to be found in the second volume of this work. In the pages which follow, syphilis will be considered from the earliest of its constitutional manifestations throughout its career, beginning, therefore, with the so-called secondary period.

The Stage of Invasion of Systemic Syphilis.—After the appearance of a chancre, from forty to fifty days usually elapse before the appearance of the first syphilitic eruption. This period may be shortened to three weeks; and, in exceptional cases, prolonged to several months. There is strong reason to believe that it may be prolonged under the influence of mercury. In it the chancre commonly progresses from complete evolution to involution; and, when there has been ulceration of that lesion, to cicatrization. Usually, also, when ten or fifteen days only of this period have elapsed, the adenopathy connected with the chancre has appeared and reached its full development. With the chancre healing or cicatrized, and with one or several of the neighboring glands, possibly their lymphatics also, in a state of painless induration, the concluding three-fifths of this period is one of apparent inactivity of the disease. It has been called for that reason a second incubative period of the disease. In the view of the inexperienced, the subject of the disease at this time may be possibly regarded as in a condition of health. Careful examination, however, reveals usually the following significant symptoms:

(a) *The Chancre Features.*—If the chancre be examined it will be found, if recognized at all near the conclusion of the period, either ulcerated, cicatrized, represented by a sclerosis, or preparing for transformation to a lesion of secondary syphilis. Sometimes a deeply ulcerated and formidable chancre persists as such till the complete evolution of secondary syphilis; oftener, before the date of such evolution, a previous ulceration has resulted in a tender cicatrix surmounting one of the several grades of induration which characterize the primary lesion. In yet other cases, without any distinct ulceration, the characteristic sclerosis of the disease persists (upon the genital region, finger, lip, etc.), ranging in bulk from a parchment-like thickening to a large nut-sized semi-solid mass usually freely movable upon the tissues beneath. Careful search for this sclerosis in every suspected region should be made in all first examinations of a patient at this period. In yet other cases the chancre is represented by an erosive lesion capping any form of sclerosis which, participating in the process of systemic evolution of symptoms, soon exhibits an elevated floor which may be covered with a whitish pellicle resembling the surface of a mucous patch, and be thus in fact changed to a true granulating mucous patch, the so-called transformation of chancre *in situ.* In all or any of such events, just prior to the evolution of secondary syphilis, there is often a marked, pathological activity of some sort in the chancre-site, the sclerosis becoming larger, the declining maculopapule more vivid, the ulcer deepening or reopening, or the superficial erosion becoming a smooth, granulating surface with an opalescent pellicle spreading over its area.

(b) *The Lymphatic Glands and Vessels.*—With very few exceptions one or more, usually several, of the lymphatic ganglia nearest the site of the chancre are found enlarged and indurated in this invasion-period. From the tenth day after the appearance of the primary lesion to the conclusion of the invasion-stage (that is, the date of appearance of the first syphiloderm) these symptoms persist. In general, it may be said that the first half of this period is required for complete evolution of the local adenopathy which in the latter half may be somewhat less conspicuous, but which yet often, at the termination of this stage, exhibits the evidence of pathological activity described above. In some cases the glands become swollen, tumid, and tender at the onset of general symptoms. The induration of the glands may persist afterward for months, the duration of the syphilitic bubo depending somewhat upon the treatment pursued. Suppuration of these indurated glands is very rare. The lymphatic vessels in anatomical connection with such glands may also undergo this specific induration, and be represented by dense quill-sized cords, single or multiple, reaching from the site of the chancre to the single lymphatic gland or cluster of glands which are superficially involved.

Besides this persistent indurated condition of one or several of the glands near the chancre-site, noticeable in the invasion-stage of general syphilis, there is usually appreciable toward its conclusion a remarkable and often suddenly occurring engorgement of the superficial ganglia. This symptom is not of local but of systemic importance. It is related less to the chancre than to the general oncoming syphilis. It is an early and almost constant symptom of general infection, often, as just described, particularly conspicuous prior to the evolution of the first syphiloderm; at other times, not fully developed till such early symptoms have been declared, and in both cases usually persisting for some weeks after its appearance.

Reference is made to a tumid and engorged, very rarely indurated, often softish condition of the chain of lymphatic glands extending along the posterior border of the sterno-cleido-mastoid muscle, or of the post-auricular, suboccipital, epitrochlear, or submaxillary glands. These glands, usually so small as to be scarcely recognizable by the finger passed over the skin, may increase till they are of the size of a bean or a small nut, and are even conspicuous to the eye of the observer. The two glands beneath the occiput are often very significantly enlarged in this way, irrespective of the occurrence of any lesion upon the scalp or vertex. This general engorgement of certain special lymphatic ganglia is often symmetrical, the glands, for example, behind one ear, or over the mastoid process, corresponding in size and firmness to those of the other side of the body. Occasionally this engorgement of glands in special regions of the body is proportioned in extent to the syphilodermata developed in contiguous regions, of the scalp, for example, where the suboccipital ganglia are affected.

(c) *State of the Blood.*—Syphilis, though often popularly described as a "blood disease," is actually one in which but very few alterations can be demonstrated in

the blood; and these but for a relatively brief period of its long course. Grassi, Wilbouchewitch, and Mélassez have by the process of repeatedly counting the number of red blood-corpuscles present in small selected portions of a drop of that fluid, determined that these constituents of the blood were from one-half to one-seventh fewer in number, in certain stages of syphilis, than in the average of sound health. With this proportionate decrease in the number of the red corpuscles, there is a relative increase in the number of the white globules. This change is characteristic of the early stage of syphilis only. It is often especially noticeable just prior to the evolution of the first syphiloderm. If syphilis is ever demonstrated to be caused by a specific bacillus, it will be found doubtless that, in the period under discussion, these micro-organisms are multiplying, and by the avenue of all the vascular channels gaining access to distant parts of the body; even, it may be supposed, to special regions where months later a tertiary gummatous product may form.

(d) *Chloro-anæmia.*—The chloro-anæmia which is the result of systemic intoxication in syphilis occurs from time to time in most well-marked cases of the disease. It may be an early or late symptom, and in grave and so-called galloping cases is throughout a marked feature of the malady. In tertiary and ulcerative types of syphilis, it may depend more upon the local symptoms than upon the general condition, and, in some cases, is without question a resultant of the long-continued inroads of the poison upon the general health.

This chloro-anæmic, anæmic, cachectic, or asthenic state is often conspicuous in the invasion-period now under consideration, with mild or grave symptoms, particularly in persons of a naturally weak constitution, or in those prostrated by other previous disorders. Often, just before the appearance of the earliest syphiloderm, the patient exhibits a pallor of the face, accompanied by a discolored, muddy, leaden, or saffron-like tint of the skin. With this there may be emaciation, weakness, and vague rheumatoid pains in different parts of the body (substernal, plantar, temporal, tibial, etc.). There is anorexia, and the patient will often describe his condition as one of "biliousness." In exceptional cases there is decided icterus, with yellowish conjunctivæ and urine of high specific gravity and heightened color. With this condition may be associated the ganglionic engorgement already described; the characteristic induration of the glands nearest the chancre; and the persistence of the initial sclerosis as a dense ridge, button, plaque, nodule, agglutination of tissue (digital chancre), or thin circumscribed sheet ("parchment" form of induration).

(e) *Syphilitic Fever.*—Recurrent, remittent, more or less persistent, and even intermittent elevations of temperature are of frequent occurrence in syphilitic subjects, more particularly in the early stages of the disease. Greater stress is laid upon this by certain English authors than the subject seems to deserve.

From one week to a fortnight before the first syphiloderm appears, with and without the icteroid, cachectic, or anæmic hue of the skin described above, the bodily temperature may rise to any point from 101° to 105° F., the lower figures representing the average of all cases where any such form is recognized by the physician; the higher, cases characterized by a tolerably profuse first exanthem of syphilis. Usually this is a transitory symptom of the disease; but at times it persists for weeks. In cases, it is preceded by a sensation of chilliness or distinct rigors. When remittent, the exacerbation is usually vespertine. There is commonly coincident thirst, malaise, *courbature*, and osteocopic pains with headache and backache. In some cases, the febrile state is so insignificant as to attract no attention.

SYPHILODERMATA (syphilides, cutaneous lesions of syphilis).—The skin-symptoms of syphilis are numerous, widely different in type and career, and of the highest importance in the diagnosis of the disease. In any given case of syphilis, the greater number of skin-lesions are displayed during the first two years after infection, that is, during the so-called secondary stage of the disease. They, however, occur often in grave forms in the late or tertiary period of syphilis.

General Characteristics of the Syphilodermata.—The skin-lesions of syphilis resemble the skin-lesions of almost every non-syphilitic disorder, yet differ from the latter in certain special features. The study of these differences is essential to the recognition of the identity of the syphilitic exanthem. Their characteristics, generally considered, may be classed as follows: (1) Absence of subjective sensations. For the most part the syphilodermata are not accompanied by pruritus, or sensations of burning, heat, pricking, etc. Notable exceptions to this rule may be found, but it is fairly constant of application, and due to the chronicity of the syphilitic exanthemata, their remarkable tendency to recurrence, and their striking amenability to treatment. (2) Career. They are rarely pyrexic; their course is essentially chronic; they are exceedingly liable to recur; and yet, as distinguished from the lesions of epithelioma and lepra, they are relatively rapid in evolution. They are greatly influenced by treatment, and are hence rarely seen when unmodified; but it is highly probable that all of them have, within variable limits, a cyclical career which would be pursued in most of the cases if no interfering agent modified their evolution. (3) Polymorphism. Multiformity of lesions, that is, the occurrence of multiple lesions of different elementary forms at one time upon the same person, is characteristic of several diseases of the skin, including syphilis. In the latter, papules, tubercles, pustules, ulcers, and maculæ may coexist upon the skin of an infected individual, who thus presents a striking contrast with the psoriatic patient, for example—the skin of the latter being possibly extensively covered with exclusively squamous lesions. (4) Color. The color of a cutaneous exanthem differs not only in different individuals of different color-type (blonde, brunette, African, etc.), but also in the same individual from year to year; *e.g.*, the lupous patch of childhood differs from the same occurring at puberty. This is true of the syphilodermata, whose color exhibits the widest range of differences under different circumstances. Certain combinations, however, of the brown, the purple, and the duller hues of other colors are especially striking when seen in syphilodermata that are typical also in seat and configuration. The so-called characteristic color of the syphilodermata has been compared with that of raw ham and of coffee, shades which, when at all distinct, are highly suggestive. After complete involution of many of the syphilodermata, especially those seated on the lower limbs, the deeper pigmentations, suggesting chocolate, coffee, or ink in color, are often recognized. Most of these deeper tints are gradually and completely removed in the months or years that succeed complete involution of the lesion. (5) Contour. Many syphilitic lesions of the skin have a remarkable tendency to assume, wholly or in part, when grouped, a circular outline. This contour is often preserved when there has been both a grouping of elementary lesions and subsequent metamorphosis or degeneration of the lesions thus grouped. In this way the figure-of-eight, the letter S, the dumb-bell, the kidney, and the horseshoe may be represented in outline by syphilitic papules in groups, ulcers, crusts, and even cicatrices. (6) Site. Any part of the skin of the human body may become the seat of a syphiloderm; and, indeed, the entire surface may be thus invaded, either by simultaneously evolved lesions or by rapid extension from one point to another. Syphilis may, however, affect for long periods of time a single region of the skin exclusively. This region may thus be preferred as the result of local irritation; for example, the palms of the syphilitic handworker; the uncleansed anal region of the syphilitic infant; and the mouth of the syphilitic tobacco-chewer. The so-called "corona veneris" is a group of dull-reddish, scaling papules on the forehead, which are peculiarly significant in male patients where the lining of the hat irritates the brow. (7) Amenability to Treatment. Mercury more particularly, and to a less extent the salts of potash after ingestion, are regarded by many practitioners as tests of the syphilitic character of any exan-

them. There are few eruptions which amend under treatment of this character as readily as do the syphilodermata, but it is an error to conclude that the latter only are thus manageable. The almost infinite variability of the skin-picture in syphilis is largely due to its modification in this way by an appropriate therapy. (8) Characters of individual lesions. The scales of syphilis are rarely lustrous or nacreous; they are commonly small, dirty gray, or darker in color, and rarely very abundant. Syphilitic papules are small or large, but often remarkable for a collarette of dirty, whitish scales surrounding their bases. The crusts of syphilis are apt to be dark-hued, in shades of deep-yellowish, greenish, chocolate, and black, from the tendency of many syphilodermata to ulcerate and the production in such ulcers of the pus and blood from which these colors are chiefly derived. The oyster-shell-like crust of rupia is wellnigh pathognomonic of syphilis. Syphilitic ulcers are prone to exhibit the circular outline, or traces of the reniform, figure-of-eight, letter S, and other shapes named above. The cicatrices left by such ulcers have necessarily a similar contour. They are, for the most part, smooth, supple, soft, and unattached. When recently formed, especially on the lower extremities, they are deeply pigmented in shades of chocolate and black. All, however, in time become white and lustrous, suggesting a thin sheet of mica when the centrifugal decolorization, which each very slowly undergoes, is complete.

The Macular Syphiloderm. (a) *The Macular Syphiloderm due to Hyperæmia.*—This is also termed the erythematous syphilide, syphilitic roseola, and the exanthematous syphilide. It is usually the earliest of the eruptions of secondary syphilis, commonly appearing about forty-five days after the appearance of the chancre. It is developed in the form of symmetrically arranged, roundish, oval-shaped, or irregularly outlined maculæ, from the size of a split-pea to that of a small coin, non-elevated, rosy, reddish-yellow, dusky-red, or salmon-and-red, disappearing under pressure. Often at the outset it most resembles a slight mottling or marbling of the surface, and at times requires for its recognition careful observation on the part of the physician. It is probably more often unnoticed by the patient than any other symptom of syphilis, at times escaping observation entirely. It may be generalized, but is usually most conspicuous on the belly, loins, chest, and back. In well-marked cases the face (brow, temples, chin), back of the neck, and extremities, including the palms and soles, are conspicuously marked with it. It may be accompanied by the syphilitic febrile symptoms already described, substernal and other pains, engorgement of the cervical ganglia, mucous patches of the mouth, and other symptoms peculiar to this period. It may persist for a week and fade; or recur in fresh maculations. As the eruption survives, it is more persistent in color under the pressure of the finger. It is decidedly and promptly amenable to mercury. It is not to be confounded with the exanthematous fevers (the thermometer readily indicating the difference); nor with urticaria and the medicamentous rashes, which are more acute in type and accompanied by well-marked subjective sensations; nor with the yellowish patches of tinea versicolor, where a vegetable parasite is visible under the microscope. None of these affections exhibits the other signs of syphilis present in the person displaying the erythematous syphiloderm. The chief diagnostic danger, however, in this connection lies in ignoring, in certain cases, the special character of this indolent, scarcely appreciable exanthem, which rarely attracts attention by subjective annoyance, rather than in any difficulties in determining, after its discovery, to what special disease it is due.

(b) *The Macular Syphiloderm due to Pigmentation.*—This is also termed by some authors the pigmentary syphilide. It occurs in an irregularly circular, ill-defined reticulum, of brownish or chocolate shaded maculations, the color of which does not fade under the finger. Often there is unusual whiteness about the pigmentations, centrally or peripherally situated, Dr. Fox, of New York, having shown that after the central pigmentation occurs there is a centripetal decolorization with deposit of pigment in excess in the interspaces of the original maculæ. The eruption is common about the neck and shoulders of blond women. The author has seen very perfect illustrations of this condition in concentric circles of large pin-head-sized maculæ, alternating with rings of pigment, in Chinese subjects of syphilis. These lesions are obstinate under treatment, and are by many authors not included among the true exanthemata of the disease. They are rather curious pigment-anomalies, occurring in syphilis as in other diseases influencing the nervous centres.

The Papular Syphiloderm.—The papule is the type of most of the syphilodermata. Many of the others are evolved from it; and it is probable that a large proportion of chancres and most mucous patches, condylomata, tubercles, and similar lesions are essentially papules which have been modified by the accidents of site, moisture, heat, etc. Syphilitic papules are circumscribed elevations of the surface, ranging in size from a millet-seed to a split-pea. They may occur as the earliest cutaneous symptom of the disease in its secondary stage, or be developed from the erythematous syphiloderm described above. They may be small or large, pointed or flat, disseminated or in groups.

The Small Acuminate, Papular Syphiloderm ("syphilitic lichen," miliary papular syphilide).—This eruption appears in the form of pointed, firm, circumscribed papules the size of a pin-head or of a millet-seed, often copiously developed, with or without febrile symptoms, over the belly, chest, arms, back, and extremities. In color they vary from rosy-reddish to mulberry or purplish shades, the hue differing widely in light and dark skins. Often the outer layer of the stratum corneum of the epidermis is slightly separated about the individual papule, which is thus surrounded by a faintly defined collar of scales. Often, also, when irritated they exhibit a minute vesicle, pustule, or scale at the apex. Where numerous, they are usually symmetrical and very closely set together. Brownish-red blotches are apt to follow their involution. The eruption may persist for months, and, with or without relapses, may appear in circular or semicircular groups, a ring of minute papules partly or wholly surrounding a confluent central patch.

The Large Acuminate, Papular Syphiloderm.—The small lesions described above may be, in special localities, developed to lenticular dimensions, retaining the conical apex. They may be seen often on the back, shoulders, and chest as purplish red rather than bright red in color, especially in the coarse skins of male patients. They may develop at the apex minute pustules whose involution leaves a small crust capping such papular lesions. They should not be confounded with iodic acne.

The Small Flat, Papular Syphiloderm.—This eruption is made up of roundish or oval, reddish to deep brownish, distinctly circumscribed and softish papules, from the size of a large pin-head to that of a split-pea, and having a flat surface. They are often seen on the chest, face, buttocks, extremities, palms, and soles, and are frequently found near the mucous outlets, though decidedly less often grouped about the mouth and nose than are other lesions to be described later. They may be few, or developed in a copious exanthem. They may be covered with a thin seborrhœic crust, after whose removal is exhibited one of the characteristic and almost indescribable color-shades peculiar to syphilis, a lucent mixture of red, brown, and purple, suggesting the varnished section of a raw ham. They may be fringed or capped with scanty, dirty-yellowish scales. Bumstead and Taylor describe this eruption as rarely occurring in cachectic subjects with a diphtheroid deposit over the papules, covering thus a granulating or superficially ulcerated surface.

Cicatrices seldom follow its involution under mercurial treatment. It commonly requires a week or ten days for complete development and, though occurring as an early syphiloderm, may relapse in any stage of the secondary period. Circinate forms of grouping, with an unchanged central area of integument, are rather more distinct in relapsing than in early forms of the exanthem. These are readily distinguished from psoriasis by the absence of

the abundant nacreous scales of the latter disease, with a history of clearing, not of a primarily cleared centre.

The Large, Flat, Papular Syphiloderm.—This eruption appears in the form of distinctly circumscribed, vivid or purplish-red, flat or slightly globoid papules, disks, "buttons," or nodosities, from the size of a pea to that of a small coin, many of which distinctly exhibit the quality of color seen in a new copper penny. They may become scaly at the surface or the base, or become granular, moist, and secreting in these situations. They are insensitive, and rarely productive of pruritic sensations. It may be developed as a first or later general syphilitic exanthem, or be evolved from the macular lesions of the erythematous syphilide, or, very conspicuously and commonly, in the middle of the exanthematous period of syphilis, with a primary or relapsing and abundant crop of lesions in some special locality—the face (alæ of nose, forehead, mouth), palms, soles, axillæ, buttocks, and extremities. Upon the forehead these lesions are apt to form the so-called corona veneris, glazed papules of coppery hue, arranged often in a line above the brows. They may develop an elevated rim and sunken centre; may ulcerate, especially in cachectic subjects or in localities subject to unusual moisture or irritation. Rarely gyrate and serpiginous lines of these papules are to be seen in special localities, *e.g.*, about the non-bearded lips and chin, or the axilla, where they may form rings. They are to be distinguished from certain isolated psoriatic patches, circinate in outline, (1) by their color, as distinguished from the more vivid hue of psoriasis; (2) by their scanty dull-hued scales; (3) by the history and concomitant symptoms of syphilis.

Syphilitic papules of all types may undergo any one of the following transformations, whose features may often be recognized at one and the same time in the course of the disease:

(1) The evolution of papules may, as a result of hyperplasia or vegetation, proceed to the production of the larger lesions recognized under various titles—warts, papillomata, condylomata, frambœsioid vegetations, etc. In this way isolated or confluent, softish, warty growths, light or deep reddish in color, freely furnishing a secretion, often of most nauseous odor, may cover large surfaces of the body or a single region only (scalp, anus, genitalia). These may be crusted from desiccation of the puriform mucus which smears them; in other cases ulceration ensues.

(2) The evolution of the papules, as a result of the same processes in special situations, results in the production of broad, flat lesions. These are the results merely of the vegetative process occurring where mucous or cutaneous surfaces are in such close apposition that elevation of the lesion is restricted and lateral expansion only is possible. In this way are produced the true condyloma, and the pinkish, whitish, and softish lesions known as the mucous patch of the skin, the vegetating mucous patch, *plaque muqueuse*, etc. They are well-defined, slightly raised, flattened disks, from the size of a bean to that of a large coin, their whitish color largely due to the muco-purulent secretion with which they are smeared, and which furnishes the characteristic, disgusting odor of these lesions. Heat, moisture, friction, perspiration, and neglect of the bath are the fertile agents in their production in the axillæ, perineum, groins, the inner faces of the thighs, about the vulva, and elsewhere.

(3) Papules may scale at apex or base, and the scaling become so significant a part of the process that the papular character of the lesion is almost disguised. In this way is produced the papulo-squamous syphiloderm. The scales are commonly scanty, desiccated, dirty gray in color, often attached, rarely freely shed from the surface. Beneath them may be seen elevated papules of the so-called copper color, having the smooth, glazed surface of such lesions, or dull-red maculæ. Very rarely, indeed, the surface is granulating.

Palmar and Plantar Syphilodermata.—Syphilitic papules of the palmar and plantar surfaces are peculiar: 1, Because of the unusual thickness of the epidermis of the region affected; 2, because of the intermittent friction, contact, and exposure to which the organs are subjected. They may be early or late, transitory or peculiarly obstinate, and recurrent lesions. Careful inspection of the palms of the majority of patients exhibiting a copious macular exanthem will result in the detection of a few pea-sized discolored blotches in this region, which often cover themselves with a thin, slightly adherent scale. In greater approximation to the type of the average cutaneous papule, firm, circumscribed, dull-reddish, and distinctly elevated lesions, from the size of a large pin-head to that of a pea, are often seen in the same region. A variation from this type produces the dirty-whitish, corneous, epidermal masses embedded in the palms and soles like foreign bodies, and almost as readily separable. These are arrested forms of complete evolution of the syphilitic papule in the palms and soles. When progressing, unmodified by treatment, they become depressed and poorly defined in outline, coalesce so as to form circumscribed patches, from the size of a coin to that of an egg or larger, with newly developed outlying lesions. The next features are unquestionably impressed upon the patch by the traumatisms and stretching of the infiltrated skin. Scaling follows, centrally and at the periphery; fissures form in the lines of the furrows; ulcers develop centrally situated, circular, oval, or stellate in outline. A purplish-floored ulcer is often seen here, its contour suggesting the fracture of a pane of glass. Recurrent and abortive attempts at reproduction of the palmar and plantar epithelium result in the formation of strata of ragged-edged epidermis, which irregularly fringe the deep losses of tissue. The entire palm or sole may be involved, and the process gradually sweep up to the wrist or ankle, and over the digits, affecting also the nails. The dorsal surfaces are occasionally involved, but always by extension from the palms or soles. Psoriasis limited to the palms and soles is of exceedingly rare occurrence; the specific lesions of this region are far more common, and are often accompanied by other unmistakable signs of syphilis with a history of infection. Squamous eczema is at times limited to the palms and soles, but, in the vast majority of all cases, affects the entire region, including the palmar faces of the digits, and is accompanied by itching.

The Pustular Syphiloderm.—Pustules occur as early and late manifestations of syphilis, being, however, less frequently observed than the lesions just described. They are of the size of a pin-head to that of a bean, transitory or persistent, with mild or grave symptoms, and may originate as macules or papules, be isolated or grouped, scanty or abundant, and result in crusting, ulceration, and cicatrization. "Papulo-pustular," "pustulo-crustaceous," and similar terms are employed to indicate these mixed forms. Authors have also employed the phrases, "acne-form," "variola-form," "impetigo-form," "ecthyma-form," etc., to designate the several varieties of the pustular syphilodermata. These terms are here purposely omitted, for the reason that the several diseases whose names are selected for comparative purposes are represented by lesions widely varying in the different stages of each disease, and exhibiting different features in different individuals. The phrases "syphilitic psoriasis," "syphilitic eczema," etc., are similarly discarded, as tending to contribute to the same confusion in the mind of the practitioner and student.

The Small, Acuminate, Pustular Syphiloderm.—These are of the size of a pin-head and larger, vivid or dull-red, roundish, rapidly or slowly formed, and superficially seated, isolated, or well-nigh confluent pustules, which may be copiously developed in a general exanthem with syphilitic fever, or, more commonly, recognized in clusters about the regions where the pilo-sebaceous follicles are large and abundant. They may begin as macules or papules. The apex of each becomes yellowish green as the pus forms, which may desiccate into minute crusts or may cover underlying ulcers of similar size. They may assume at times the circinate outlines. They are often seen on the scalp, face, neck, and trunk; rather less frequently on the extremities. Involution is often followed

by rather persistent pigmentations; more rarely by minute atrophic scars.

The Large, Acuminate, Pustular Syphiloderm.—Yellowish-brown, conical pustules, of the size of a pea and larger, may develop slowly from the small lesions just described, or rapidly from maculo-papules. They are usually superficial in situation, become crusted at the apex, and, after the formation of the crust, may be depressed centrally. Ulcers frequently form as the result of this process, whose healing may leave small cicatrices. They form over the scalp, face, neck, shoulders, and extremities; and are usually the expression of either a graver form of syphilis or of a syphilis less judiciously managed than the lesions previously described.

The Small, Flat, Pustular Syphiloderm.—This is a relatively frequent manifestation of syphilis, beginning by the development of circumscribed macules or maculo-papules, which rapidly form flat, roundish pustules, the size of a pin-head and larger, and superficial in situation. They are usually grouped, isolated, and at first not confluent; but their reddish and purplish areolæ become fused, and the whole is soon covered with a flattened, dirty-yellowish, and greenish crust, which commonly surpasses the limits of the patch. On the removal of the latter, a violaceous surface is seen, granulating, puriform, occasionally superficially eroded, possibly ulcerated. These lesions are often seen in and about the scalp, and about the lips, chin, beard, and trunk. In persons of weak constitution, and not properly treated, the face will occasionally be found almost completely covered by an irregularly crusted mask, formed in the manner described above, the pustulo-crustaceous lesions occasionally spreading in a serpiginous course, or forming the familiar rings, or segments of rings, seen in the grouped syphilodermata.

The Large, Flat, Pustular Syphiloderm.—Pustules, the size of a bean and larger, deeply seated, or projected from the surface, may represent any of the forms described above, proceeding to full evolution, usually in cachectic subjects. They represent, also, the later periods of the so-called secondary stage of syphilis. Often they have dark-red, deep, infiltrated bases with violaceous areolæ; and the pus finally desiccates into thick, bulky, greenish, or blackish crusts, firmly adherent to the edges of a foul-based, hæmorrhagic, or pus-filled chamber beneath; or, after bursting, they leave open, sharply cut ulcers, with blood or pus freely formed from an exposed, eroded, sloughing surface. The ulcerative phase, with its crust, is, indeed, often the conspicuous feature of the process, the deep-seated pustular lesion which ushered in the mischief being thus speedily metamorphosed. These ulcers may be few or numerous, superficial or deep; and may be in outline circular, oval, semicircular, dumb-bell-shaped, etc. Their cicatrization commonly results in a typical syphilitic cicatrix.

Rupia.—This term was at one time employed as the name of a distinct disease. It has long since lost any applicability to non-syphilitic disorders. Every rupia should to-day be recognized as syphilitic. Indeed, according to modern usage, the name merely describes certain peculiarities in the syphilitic crust. The explanation of its former temporary and unmerited elevation to the dignity of a disease supposed to have a separate entity, is to be found in the fact that occasionally a patient will be extensively covered with rupioid crusts, who exhibits no other symptom of syphilis.

The crusts thus named may be few and small, or large and generalized. First appear macules, then pustules, whose contents desiccate into crusts of greenish, brownish, and blackish shades, covering and nicely fitted over underlying ulcers. The ulcer slowly spreads at the periphery, and its purulent and hæmorrhagic secretions add by desiccation to the bulk of the crust. The additions are made beneath and laterally to the under surface and edges of the closely adjusted crust, which hence becomes a conical, stratified shell, usually with a slightly concave inferior surface, the whole often compared to an oyster-shell. Each succeeding stratum of incrustation, from the conical apex of the crust to its base, represents, therefore, a somewhat larger ulcer and a somewhat more abundant secretion. There may be an outlying violaceous areola. The indolently spreading ulcers beneath correspond in size to the shells which cap them. They may be superficial or deep, but usually have a foul, purulent, or hæmorrhagic floor, and punched-out edges. Grave as is the condition of the patient who is extensively covered with the largest-sized rupioid lesions, the best of results may be anticipated under proper hygienic management and energetic treatment.

The Vesicular Syphiloderm.—Vesicles are rarely the results of the syphilitic process in the skin. They usually point to an exudation more acute in type than that recognized in the indolently traversed cycle of syphilis. Occasionally miliary papules exhibit a vesicular apex containing a droplet of serum. Circinate and other groups of vesicles are described by French writers as of occurrence in this disease. Two explanations of the so-called vesicular lesions are at hand: first, the development of eczema, herpes, etc., in infected persons—phenomena not rarely observed by an expert; second, the occurrence of vesicular lesions provoked by externally applied or internally ingested medicaments employed for the relief of the systemic disorder.

The Bullous Syphiloderm.—Discrete, roundish bullæ, from the size of a pea to that of a small egg, appear simultaneously or in crops upon the syphilitic skin, in consequence of a more or less circumscribed elevation of some portion of the epidermis by accumulation of a clear lactescent serum, pus, or blood. The contents usually desiccate into bulky, adhesive, stratified, greenish or dark-colored crusts, which may cover granular, eroded, or ulcerative surfaces. Often they are surrounded by a violaceous halo. The ulcer, after removal of the crust, may spread in depth or area, or cicatrize; this according to the vigor of the patient and the treatment pursued. Lesions of this sort are rather more often recognized upon the extremities than elsewhere, in consequence of the greater distance of the latter from the centres of circulation. They are more often encountered in late periods of secondary or tertiary disease, and in cachectic subjects. They are for these reasons most often seen in the tender skin of the infant who is the victim of hereditary syphilis.

It should never be forgotten, when making a diagnosis of the bullous syphiloderm, that the iodide of potassium, in exceptional cases, is capable of producing such lesions in typical aspect when administered to the syphilitic as well as to the non-infected patient. American observers chiefly have called attention to this important fact, among them Drs. O'Reilly, Graham, Morrow, and the author.

The Tubercular Syphiloderm.—Hyperplastic evolution of the papule, besides producing the aberrations from type already described, may also result in the formation of definitely circumscribed, deeply seated, single or multiple, bright-reddish or livid, solid, cutaneous, or more commonly subcutaneous, lesions, from the size of a pea to that of a small egg, known as tubercles. These are usually late secondary, or early or late tertiary syphilitic symptoms, which, in consequence of difference of involution, are divided into two classes.

The *resolutive tubercular syphilide* is characterized by: Slow evolution without marked subjective symptoms, disappearance after absorption of the plastic infiltration commonly involving the entire thickness of the derma, and the production, without previous ulceration, of an indelible scar. The lesions begin as superficial, reddish, and roundish gummatous nodules, the size of a pin-head, which, as they attain the larger dimensions named above, become flatter, smoother, more lustrous, and more deeply tinted. They are largely facial or cervical in situation, but may also spread over the trunk and extremities. They are often free from scales, except when seated upon the palms or soles, in which situations they may be covered with thick corneous plates beyond whose borders can be recognized a violaceous halo. These lesions may be generally disseminated, or grouped in distinctly circumscribed patches, either circular in outline or exhibiting some modification of the latter (*e.g.*, the reniform, horse-

uously smaller size of the scar-like depressions, usually furnish a clew to the distinction sought to be established.

THE GUMMATOUS SYPHILODERM.—Single and multiple, isolated or massed nodules, from the size of a pea to that of an egg, or larger, originating simultaneously, but commonly invading the skin as they develop, occur in late, rarely in early, periods of syphilis, and are termed gummata in consequence of the gummy material they furnish when disintegrating. They are rarely numerous, often not more than from two to six affecting a single patient. As an exceptional fact, hundreds may be seen covering different regions of the body. They are peculiar to syphilis; in other words, they do not pursue, in the course of other affections, the same classical cycle of evolution and involution. Yet they are really syphilitic tumors, allied, on the one hand, to the hyperplastic process which produces the papule and tubercle; and, on the other, to the histological type of tumors in general. Pathologists have some ground for believing that the so-called gummous material of this lesion is to be recognized in the nodules that glue the iris to the capsule of the lens, and even in the neoplasm that constitutes the mass of the initial sclerosis.

After development, gummata may for a long period of time be perceptible beneath the skin as smooth, circumscribed, insensitive, firm nodules, undergoing no change. Later, they become slightly painful; there is passive hyperæmia of the overlying skin; attachment between the skin and the tumor is effected; then follow, usually, fluctuation and evacuation (spontaneously or by surgical interference) of inspissated blood and pus, or of the contents of a true, circumscribed abscess. The gummatous mass constituting the tissue, bathed in pus and blood, is slowly or rapidly removed by this process, in the course of which is formed the gummatous ulcer. This has the circular outline, precipitous edge, sloughy floor, foul secretion, livid halo, and phagedenic tendencies already described as characteristic of the syphilitic ulcer in general, with this special added feature, that it is particularly deep. Its floor rests on subcutaneous tissues. It involves fasciæ, periosteum, muscles, large vessels, bursæ, nerves, bones, tendons, and other important tissues. Its walls, carefully inspected, often exhibit the sharp and resisting edge of a dense aponeurosis, the glistening white border of a tendon, or the firm periosteum sheathing an osseous plate.

Occasionally gummata are lodged in, rather than beneath, the skin, the firm, movable mass being then readily defined by palpation. Whether superficial or deep in situation, they may undergo complete resolution. When disintegrating by ulceration, they may go on to produce those extensive and formidable losses of tissue, complicated with erysipelas, pyæmia, etc., in the subjects of cachexia and alcoholism, which make syphilis, in some of its manifestations, a veritable scourge. Though occasionally numerous, not more than from six to eight are usually to be recognized in the person of a single patient. They are most frequently developed upon the lateral surfaces of the legs, and, next, proportionally after these, over other parts of the extremities, the face, scrotum, buttocks, neck, and the breasts of women. The importance of their recognition in the last-named situation, when the question of cancerous and other malignant tumors of this organ is presented for consideration, can scarcely be overestimated. The author has seen a gumma, the size of a turkey's egg, in the breast undergo complete involution under specific medication only.

The elephantiasic aspect of the face and legs of certain patients who are afflicted with extensive gummatous tumors and infiltrations of the cutaneous and subcutaneous tissue is a matter of great moment for the diagnostician. In almost every community there is some such patient, with a striking deformity, the nature of whose malady has been altogether unknown for years. In such cases there is often an obscure history, which, perhaps, the expert alone has been able to correctly interpret. The patient has been supposed to be the victim of "elephantiasis." The nose, lips, cheeks, and chin are possibly densely thickened, distorted, empurpled, and irregularly ridged and seamed with nodules, scars, and ulcers; or the leg is in the pachydermatous condition seen in the "Madura foot" and other diseases. It is a large, unwieldy organ, ridged, of cartilaginous hardness, furrowed, and covered with an integument looking like the bark of a tree. Careful inspection, however, always reveals in this mass the typical cicatrices of ancient gummatous ulcers, and the traces of new and old nodules buried in the hypertrophied and œdematous mass. Here, as in so many other of its formidable aspects, syphilis reveals its amenability to proper management. The changes that can be wrought by treatment in these apparently desperate cases are in the highest degree satisfactory.

THE SERPIGINOUS SYPHILODERM.—Though not distinguished by the name of an elementary lesion whose preponderance might justify such a position, this syphiloderm has an individuality requiring its separate consideration.

In its superficial forms it is preceded by the appearance of small, pointed or flat syphilitic pustules, which form a circular or partially circular group of lesions in disks of the size of an egg and larger. These disks are soon covered with a yellowish, greenish, or blackish crust, which gradually clears from the centre, leaving there a granulating or smooth, reddish or normally tinted, atrophic or only superficially altered integument, surrounded by an entire or broken ring of attached crusts, beyond which is a livid halo. Underneath this latter is a superficial, centrifugally spreading ulcer, uniformly annular in contour, or here and there broken by bridges and islands of unaltered skin. Often this annular ulcer is seen to be composed of roundish excavations, the size of a pea and larger, arranged circle-wise, with confluent crusts. In other cases the crust is scarcely more than a narrow ring, no broader than the smallest penknife-blade, which, as it spreads centrifugally, leaves cutaneous areas of former invasion, the size of the palm and larger, pinkish-red or slightly pigmented in color, at times decidedly cicatriform, at other times texturally unaltered. In this way an entire buttock or limb, or the face, may be progressively involved.

The deep serpiginous syphiloderm always spreads, as Bumstead and Taylor have well indicated, from a gumma or other late lesion of syphilis. A deep ulcer results, which attacks the subcutaneous tissues. The centre is soon represented by a tender or firm scar; the advancing edge by a thick, greenish or blackish, adherent crust, covering a deeply cut circular exulceration with punched-out walls and foul secretion. The dull, purplish areola of all similar lesions is visible at the periphery beyond its advancing edge. Its progress over the skin is decidedly more serpiginous than in the direction of the radii of a circle. Here and there a kidney-shaped, or horseshoe-shaped edge exhibits a deeper excavation, or a more tenacious, bulkier, and darker crust. In yet another part of the same disk the ring may be represented by a partially cicatrized border, or a wide bridge of unaffected skin. This is a late, exceedingly obstinate, and intractable form of syphilis, leaving generally a deforming scar. It is to be distinguished from lupus (which is more often seen on the face) by its definite outline, its deep pustular, rather than nodular, elementary lesions, its sharply cut ulcerations, but, above all, by its relatively rapid progress.

MALIGNANT SYPHILODERMATA.—Syphilitic cutaneous and subcutaneous lesions are at times malignant in type, and then commonly precocious in occurrence and acute in course. They are described by Bazin and other French authors as "malignant precocious syphilides." The intensity and violence of the symptoms in these cases is in general due to the occurrence of the disease in cachectic subjects, those who are debilitated by age or previous or concurrent diseases, those deprived of the essentials of healthy living, viz., wholesome food and drink, hygienic environments, freedom from mental anxiety, and a proper adjustment of labor to bodily vigor.

In patients of this class the chancre is scarcely cicatrized before so-called tertiary lesions appear. They are

divided by most authorities into (*a*) the puro-vesicular syphiloderm; (*b*) the tuberculo-ulcerative syphiloderm; (*c*) the gangrenous tuberculo-ulcerative syphiloderm. These names are mainly groups of symptom-phrases, the lesions themselves exhibiting a wide variation indicated by both mild and grave characters.

The milder forms are really precocious, rupioid lesions following isolated or grouped pustules, which are rapidly followed by ulcers, thickly covered with laminated crusts. In a more accentuated form the malignity of the outbreak is indicated by the development of lenticular tubercles, which hasten to break down into ulcers of characteristic syphilitic edge, secretion, floor, base, and areola, which attack the face, trunk, hands, or extremities. The graver forms are precocious, tubercular, ulcerative, and gangrenous. A group of nodules in or beneath the skin surrounds itself with significant purpuric points, supposed to indicate an endarteritis of the peripheral vascular elements. The whole rapidly or slowly becomes gangrenous, showing a dry, blackish eschar, which spreads at the periphery, and insidiously, as it encroaches upon the sound tissues in the vicinity. Sometimes a line of demarcation is formed, not between the gangrenous mass and the sound skin, but between the former and a thickened empurpled zone which surrounds it. When the slough is removed, a conical crateriform ulcer is exposed, having a fœtid secretion, a sloughy floor, and markedly everted edges. The destructive process may progress till fatal results are produced, the patient succumbing to fever or marasmus and adynamia. But this is rare. Under the best treatment repair sets in, granulation is followed by cicatrization, and there is apparently complete restoration of the general health.

Cutaneous lesions and symptoms other than the forms described above are neither numerous nor important, but have been described by authors. Dr. E. B. Bronson, of New York, has described an erythanthema syphiliticum in which vesico-pustular and other lesions were grouped upon an erythematous base. Hæmorrhagic effusions within the skin occur chiefly in patients who are the subjects of hæmophilia, and who have also contracted syphilis; in children afflicted with hereditary syphilis; in patients with paraplegia resulting from syphilitic involvement of the cord (purpura of the lower extremities); and as an accident of a number of secondary and tertiary lesions. The author has seen two such cases occurring in syphilitic disease of the cord. It should never be forgotten that the iodide of potassium, when administered for the relief of syphilis, may produce purpuric spots, especially over the lower extremities.

Lastly, eczema, psoriasis, the animal and vegetable parasitic affections of the skin, pruritus, and the various dermatides, all the forms of acne due to the ingestion of the iodic compounds, and other cutaneous disorders affect the syphilitic as well as the non-syphilitic patient. Each of them exhibits its special peculiarities, apparently not at all or very slightly modified by the syphilitic diathesis, and is recognized in its identity as distinct from the manifestations of syphilis without great difficulty on the part of the diagnostician. This recognition is a matter often of the highest moment, as the anxiety and dread occasioned in many patients by the discovery of these intercurrent affections (to which the mass of mankind is subject) are out of all proportion to the real import of the symptoms presented in such cases.

TREATMENT OF THE SYPHILODERMATA.—The internal treatment of the syphilodermata is that of syphilis in general, including the use of mercury, the iodide and other salts of potassium, iron, cod-liver oil, and a nutritive regimen.

Many of the lesions, however, require local treatment. The salves which are most effectively used with this end in view contain one of the salts of mercury. Among these may be named the ammonio-chloride, in the strength of from five grains to half a drachm to the ounce (0.33–2.0 to 32.00); the red oxide, in the strength of from five to ten grains (0.33–0.66) to the same quantity; the ten or twenty per cent. oleate of mercury; the mild chloride, in the strength of from ten to thirty grains (0.66–2.0); mercurial ointment, in the strength of from half a drachm to a drachm (2.0–4.0) to the ounce; and the ointment of the nitrate of mercury in nearly the same strength. The bases of these salves may be vaseline, cold cream, lanoline (Liebreich's wool-fat), or simple cerate, a drachm (4.0) or more of glycerine being added to the ounce (32.0) of each when requisite to produce softness in the mass. Vaseline is preferably employed as a basis for salves to be applied over the scalp and hairy parts.

Besides the mercurials the tars are employed with advantage, including the oleum cadini and the oleum rusci (rectified or crude), in the strength of from half a drachm to a drachm to the ounce (2.0–4.0 to 32.0) of basis, adding an equal quantity of finely levigated prepared chalk to obtund the sharpness of the tar. These are excellent applications to palmar and plantar syphilodermata, when preceded by maceration of the affected surfaces for several minutes in water as hot as can be tolerated. Often the thick epidermal scales of these regions are best removed at the time of these macerations by the aid of a shampoo prepared by adding an ounce of glycerine to two or more ounces of the tinctura saponis viridis of the Pharmacopœia. After the shampooing with hot water, the hands or feet are dried, the salve well rubbed in, and gloves are drawn over the hands, or stockings over the feet. Other ingredients are often incorporated with such salves with excellent effect. Among them may be named salicylic acid, ten to twenty grains to the ounce (0.66–1.33 to 32.0); chrysarobin, pyrogallol, and ichthyol, in the same strength; zinc oxide and the subnitrate of bismuth, half a drachm to a drachm to the ounce (2.0–4.0 to 32.0); and the oleate of lead, in the form best known as Hebra's unguentum diachyli albi.

Powders occupy a most important place in the local management of the syphilodermata, more particularly those that are ulcerative in type. Among them may be named iodoform, hydronaphthol (1 part to 50 of fuller's-earth), and iodol, boric and salicylic acids, calomel, starch, camphor, and lycopodium. Many of these are advantageously employed over such moist lesions as condylomata after they have been washed in a lotion of chlorinated soda or carbolic acid, so as to be not only deprived of their usual disgusting odor but thoroughly cleansed.

Lotions of the kind just suggested are useful in the management of a number of the secreting syphilodermata. Others are compounded with the corrosive sublimate, one-half to one grain to the ounce (0.33–0.66 to 32.0) of bay-rum, Cologne-water, or the rectified spirit of wine. Lotions containing tar, salicylic acid, carbolic acid, and boric acid (often in saturated solution) meet the indications of many cases.

For the purpose of stimulating or otherwise dressing mucous patches and indolent ulcers, solutions of the nitrate of silver, five grains to a drachm to the ounce (0.33–4.0 to 32.0), or crayons of the solid salt may be used; or even the strong caustic solutions, *e.g.*, of the hydrate of potassium twenty to sixty grains to the ounce (1.33–4.0 to 32.0), or of nitric acid. Solutions of corrosive sublimate in tincture of benzoin, or of myrrh, one to two grains to the ounce (.066–.033 to 32.0); benzol, creasote, and solutions of the permanganate of potassium and resorcin, one to five per cent., are also useful in many cases; the first two for destructive effects, the last as antiseptic dressings.

The principles on which should be based the local treatment of the syphilodermata are those recognized in all similar non-specific affections of the skin. Of chief importance is the treatment of the disease itself, whether by internal medication, inunction, fumigation, or hypodermatic injection. To this, in most cases, may be added the local treatment with marked advantage. The scalp, hands, and feet may be often shampooed, and subsequently dressed with a salve or lotion. Pustules are to be opened, crusts removed, and small or large ulcerated surfaces cleansed, cauterized or stimulated, and antiseptically dressed. Soap and water are as imperatively required for the syphilitic as for the non-syphilitic skin.

Frequent applications of water as hot as can be tolerated are often required for the relief of pain, and the surgeon's knife is needed for opening softened gummata. In extensive syphilitic ulcerations an exceedingly valuable resource is the use of the continuous hot-water bath as employed in Vienna, the patient, if his ulcers can be in this way immersed in the water, remaining in it for hours, the bath being kept as hot as is grateful to the surface of the immersed skin. The bath is left only on occasions requiring evacuation of the contents of the bladder or of the rectum, or in order to secure sleep. Lastly, the mercurial, rubber, lead, and other surgical plasters, borated cotton, antiseptic wool (medicated with the mercuric iodide), prepared oakum, fuller's-earth, and the other articles needed to make the dressings of modern surgery, are never more useful than in the management of multiple or extensive syphilitic ulcers.

Affections of the Hair, Hair-follicles, and Hairy Regions of the Skin.—A common manifestation of syphilis is a loss of hair, in excess of the physiological defluvium capillitii, resulting in alopecia. This may be an early or late symptom, rapidly or slowly occurring, scarcely perceptible or greatly deforming, and transitory or resulting in permanent baldness.

The earliest form of alopecia may occur without local subjective or objective sensations, the symptoms being often limited to the loss of hair. It may again be accompanied by macular, pustular, papular, ulcerative, or crusted lesions of the regions affected. It may appear as early as the date of the first syphiloderm, and, indeed, may be the first significant feature of general syphilis. In other cases it is conspicuous only after the third or later month of infection. It may affect any hairy region of the body, but is more commonly noticed on the scalp, beard, mustache, eyebrows, and lashes. Upon the scalp, it is probably much more common of occurrence than of observation, since it is often first recognized in men only after the hair is cut short.

The hair may appear to be merely thinned in syphilitic alopecia, when the pilary loss is actually conformed to type. The close-shaven head of the syphilitic, affected with the early form of alopecia, presents almost always the same appearance. The scalp is then seen to be covered with irregularly circular areas of baldness, symmetrically arranged as regards the two halves of the body, these areas varying in size from a split-pea to a silver dollar. There is asymmetry, however, in the disposition of individual patches. The scalp thus affected may be apparently sound, or dry and lustreless, or, as described above, the seat of a syphilitic exanthem. When the hair is long, as in women, the striking disfigurement visible on the shaven scalp is scarcely apparent; in men whose hair has been cut moderately short the effect is that of a characteristic patchy irregularity, in which it is clear that the temple and occiput are as much affected as the vertex. The eyebrows, eyelashes, and mustache may be merely thinned, or suffer a loss in patches. The shaven beard may present an appearance nowise distinguishable from the condition of the same region when affected with alopecia areata.

The late forms of syphilitic alopecia are always due to destructive lesions of the cutaneous region covered with hairs; and the alopecia is hence usually the less important feature of the disease. Thus deep pustular, gummatous, ulcerative, and other like changes in the scalp are usually followed by an asymmetrical loss of hair, often limited to a single patch, where, after cicatrization, the resulting alopecia is remediless.

The early form of alopecia is unquestionably chiefly due to defective nutrition of the hairs in the hair-follicles, and, as alopecia areata is probably due to the same immediate cause (the remote cause being essentially different), it follows that the shaven scalp presents almost the same appearance in two selected cases of the two diseases. The bulbs of the fallen hairs are seen under the microscope to be distorted and misshapen in early syphilitic alopecia, and the hairs themselves are usually dry and lustreless. The pathology of the late forms of alopecia in syphilis is that of the syphilitic process to be studied in the tissues generally. Usually a degenerating gummatous infiltration eventually encroaches upon and destroys the hair-follicle. Syphilitic alopecia is to be distinguished from all physiological losses of hair by its sudden occurrence in persons of the age in which syphilis is most commonly encountered, its asymmetry, and its involvement of the temples and occiput equally with the vertex. A history of infection can usually be obtained, and other symptoms can often be discovered. Seborrhœa capitis, or alopecia furfuracea, is distinguished by its fatty or dry scales, and its failure to remove the hairs in distinct areas. The patches of alopecia areata strongly resemble those of early syphilitic baldness in the shaven head; the loss, however, in the former disease is more sudden, and recovery is marked by the appearance of whitish or grayish downy hairs, which is not often the case in restoration after syphilitic alopecia. The internal treatment is largely that of the secondary symptoms of the disease. The local treatment should consist of daily shampooings with hot water and the Sarg fluid soap; or, where mere stimulation is required, by the aid of the tincture of green soap flavored with lavender. After such shampooing the scalp may be anointed with scented lanoline or vaseline, or with an oleaginous lotion made by adding two drachms each of the oil of sweet almonds and glycerine to an ounce each of the spirit of rosemary and alcohol, and two ounces of Cologne-water.

Affections of the Nails, Matrix and Bed of the Nails, and Adjacent Parts.—The term onychia is applied to the changes which are first apparent in the nail; and paronychia to those which only secondarily affect the nail and primarily the matrix, nail-bed, or cutaneous folds by which the nail-substance is surrounded. It is probable that the distinction is purely artificial, both forms being preceded by alterations of tissue exterior to the nail-substance proper. These appendages of the skin are frequently affected in syphilis, both during the secondary and during the tertiary stages, and the resulting lesions may be transitory or persistent, and mild or grave in character. The course of these changes is usually chronic.

In the most frequent form of onychia (*onyxis craquelée*—dry or friable form) a portion or the whole of one or several of the nails may become dry, lustreless, grayish yellow in color, friable, rugous, irregularly thickened, traversed by furrows in one or more directions, or singularly disfigured by numerous minute pockets, from which the crumbling nail-substance has fallen or been removed by washing and scrubbing. The nails are usually tilted up at the free border and separated from their beds. Careful examination will often reveal a ridge of thickened epidermis at the sides or attached border of the nail, which may be normal in appearance or dull purplish in color and scaling; or, on pressure, a few drops of thin, ill-conditioned pus may escape from beneath it. This form is said to be more common in women. Under treatment these phenomena may disappear; and the distorted nail be pushed forward and replaced by a healthy new one. In other cases one or several of the nails are insidiously loosened from bed and matrix, and are shed without the occurrence of any appreciable change in the surrounding parts, precisely as the hairs fall in many cases of syphilitic alopecia. Sometimes, even when attached at its border, the nail is seen to be completely separated over its entire area from the bed beneath. When the nail, on the other hand, is affected with an onychauxis, it may increase to three or four times its normal bulk, a condition described by some writers as hypertrophic onychia.

Paronychia may affect the whole or a part of the nail, and be dry or ulcerative in type. In the former case a dull-purplish ridge of cutaneous tissue, in the vicinity of the nail-fold and including it, becomes indolently thickened, scaling, and fissured. Superficial ulceration may follow, with purulent or hæmorrhagic secretion and crust-formation, the ulcer spreading slightly beneath the nail at one point, the substance of that organ having already exhibited the changes due to impaired innervation. The characteristic feature of this complication is a finger with its distal phalanx having a bulbous appearance, its par-

tially altered, dirty-looking nail tilted upward or to one side, and a dry, scaling, or indolently granulating surface exhibited in the exposed part of the bed.

Ulcerative paronychia is characterized by a shallow or deep ulceration extending at the central or lateral parts of the nail-fold, matrix, or bed, bathed with a sanguinolent, thin, or ill-conditioned pus. It may begin with the dry lesions described above, or with the development of marginally seated papules or pustules. The nail may, as a result, be in lateral deviation from the axis of the phalanx, or partially or wholly loosened from its attachments. In this state it may present any of the changes seen in syphilitic onychia. The nail-bed, when thus exposed, is usually tumid, covered with a thin, puriform secretion, granulating, or the seat of an irregular, firm, and whitish, epithelial investment. Thin layers of new nail-substance speedily form over this surface if proper treatment be instituted; and, even in the cases where a distorted nail at first covers the bulbous phalanx and its purplish, tumid nail-fold, the restoration is eventually complete. In some cases the ulcer first forms beneath a crust under the free edge of the nail, and thence, when not properly managed, spreads irregularly over the matrix, the nail becoming loose and undergoing the changes already described. Care should be taken in the diagnosis of such cases to exclude trichophytosis unguium (where the parasite is recognizable under the microscope); eczema and psoriasis (in which there is no history of syphilis and none of its other symptoms); digital chancres (in which the nails are not chiefly involved); and ordinary forms of paronychia (which commonly spare the nail-bed and matrix).

The treatment is largely internal; locally the white precipitate salve [one scruple to the ounce (1.30 to 32.0)] may be applied on rags. Ulcers may be dressed with pencillings of the nitrate of silver, followed with iodoform or iodol in powder.

Affections of the Eyes.—The *bones* composing the orbit may be involved in osteitis or periosteitis, with degenerative results in the form of caries or necrosis. In this way may be lighted up an intraorbital cellulitis resulting in abscess. Nodes also occur within the orbit, and may be followed by serious consequences when productive of pressure-effects. The lachrymal passages also may be involved in obscure catarrhal changes, associated with pharyngeal lesions. Mucous and subcutaneous tissue, periosteum, and bone may be eventually implicated, with the result of producing lachrymation, epiphora, abscess, and eventually fistulæ. The treatment is by division of the canaliculi and dilatation of the canal by probes. The parts may then be treated with weak injections of the nitrate of silver, or, what is fully as valuable, two to five per cent. solutions of resorcine. When the canal is pervious to the probe, the trouble is usually due to changes in the periosteum of the nasal process of the superior maxillary bone. The frequent application of water, as hot as can be borne, to the affected parts, if required in connection with the application of fomentations, will often give relief in these cases when energetic constitutional measures are adopted. Bumstead and Taylor report syphilitic changes in the lachrymal gland sufficient to produce a species of ptosis, and also gummata of the caruncles.

The *eyelids* may be severely and extensively involved in syphilis. They may be the seat of papules, pustules, ulcers, and resulting cicatrices dragging the lids into ectropion. Syphilitic ulcerations attack the canthi and free edges of the lids, encroaching also upon the mucous surfaces. The author has seen both upper lids symmetrically involved in ragged ulcerations of the edge resembling the work of a punch. Degenerating gummata of these regions often leave disfiguring cicatrices. The palpebral conjunctiva is often the seat of mucous patches. Subcutaneous indolent nodules, the size of a hemp-seed to that of a pea, occasionally form in the lid, which may obstinately persist when treated. The tarsus is reported also by several observers to have been involved in a tarsitis syphilitica, which is at first productive of tumefaction of the lids, and later, of changes in the cartilage itself. The fasciæ and tendons of the ocular muscles are also liable to syphilitic changes, which may result in thickening, in abscess, or in fistula. All lesions of the eyelids, of secondary and tertiary type, are to be distinguished from chancres of the lid, accidents not of very rare occurrence in the large cities. In these cases there is great tumefaction, brawny, empurpled thickening (of the inner canthus usually, the part most apt to be rubbed by the finger that transports the infective secretion), and a specific induration of the pre-auricular or submaxillary gland—far more commonly the former.

The *conjunctiva* may be the seat of mucous patches, circumscribed macules, papules, tubercles, and gummata. These are, however, rare. The ocular conjunctiva is spared most of the lesions of syphilis, save when it becomes engorged with blood as a consequence of iritis.

The *cornea*, when participating in syphilitic changes, is usually recognized in the victim of inherited disease. There is found, first, slight pericorneal vascularization, in the diffuse form, with one or several centrally situated or marginal opalescent points showing in the cornea. These increase till the whole or a great part of the cornea is involved, producing thus a characteristic opacity limited to the field of the keratitis. With the keratitis of inherited syphilis are often seen the alterations in the color, size, and shape of the permanent incisor teeth, first ably described by Mr. Jonathan Hutchinson. This observer regards the permanent upper central incisors as the test-teeth. These are usually vertically and transversely shortened and thinned, with a crescentic notch at the free border, its convexity regarding the root of the tooth. This notching, most conspicuous in childhood, becomes partially obliterated by attrition in later life. The teeth are also often convergent, occasionally separated; in other cases "pegged," and again discolored in shades of a dull brown.

The punctate form of keratitis is seen both in acquired and late inherited syphilis. Intracorneal puncta, the size of a pin-head, are then visible, careful observation of which reveals the lack of lustre or grayish shade of color of corneal opacities in general.

The *sclera* may be involved (1) in an episcleritis beginning with pericorneal hyperæmic maculæ of a dull-reddish hue, with few if any subjective sensations. A circumscribed portion of the sclera may then appear thickened, and in some cases radii of engorged conjunctival vessels indicate an extension of the hyperæmia to the overlying membrane. In extreme cases the cornea, sclera, iris, and lens are involved in a common inflammatory process; cases which the writer believes originate for the most part in an iritis. (2) An interstitial, or parenchymatous, scleritis may present the features of an inflammation of the organ, or of a gummatous deposit, or of infiltration within its substance, which, following the rule in similar involvement of other organs, may undergo resolution, or degenerate into an ulcer with irregular edges, and softish, grayish floor. When the cornea also is implicated, one sees a characteristic conical area of corneal opacity, its base resting upon the involved sclera, its apex projected forward to the centre of the cornea.

Iritis.—More than one-half of all cases of iritis are of syphilitic origin, the proportion ranging between sixty and eighty per cent. of all cases. It is not only a common complication of the disease, but, as regards the loss of vision, one of the most disastrous. The symptoms of specific and non-specific inflammation of the iris are, taken *per se*, indistinguishable. Three forms are to be recognized: Simple plastic, serous, and parenchymatous. The two first named belong to the secondary period of the disease; the last is due to a gummatous infiltration of the organ. The disease is commonly unilateral in situation at the outset, but in fifty per cent. of all cases ultimately attacks the other eye. It occurs most frequently at the average age of the syphilitic subject, that is, in early adult life; and is much more frequent in men, by reason of the greater exposure of the eyes of the male to the accidents incidental to the trades and occupations of life. Simple plastic iritis is the condition in which there is, first, hyperæmia and a plastic exudate from

some portion of the iris, with proliferation of the connective-tissue elements. It may be so slight in its symptoms as to escape detection, and be then accompanied by mild photophobia and vascular injection. In other cases the symptoms are marked and distressing. There is distinctly pericorneal vascularization, sometimes subconjunctival œdema. The large, mobile, tortuous, brick-red conjunctival vessels contrast strongly with the straighter radii of delicate pinkish underlying vessels visible in the sclerotic zone and limited largely to it. Both planes of injection aid in giving a distinctly reddish color to the eye, which is evidently in a state of inflammation. The affected iris is peculiarly dull-hued, its color, as compared with its unaltered fellow, being changed in various shades according to the color natural to the organ in health. It is sluggish to the light, and often its structure is indistinguishable to the eye of the careful observer, because covered with a delicate stratum of the plastic exudate. The latter may extend also over the anterior capsule and give the pupil a cloudy appearance. The aqueous humor may also become turbid. In consequence of these changes the free border of the iris is often agglutinated, in various degrees, at one or several points, to the anterior face of the capsule of the lens, so that when its muscles contract the pupillary outline becomes irregular, being changed from the figure of a circle to that of an interrupted curve, or to semilunar, trefoil, figure-of-eight, or scallop shapes.

Serous iritis is characterized by the exudation of a serous fluid, with hypersecretion of a cloudy aqueous humor, which precipitates a deposit in the form of a delicate, opaque, punctate, or diffuse film on the posterior face of the cornea, the anterior face of the lens, and the membrane of Descemet. There is increased intra-ocular tension, the pupil is immobile and dilated, and the iris is changed in hue. There is less injection of the sclerotic zone than in the plastic form of iritis. Glaucoma may eventually result, from participation of the ciliary body and choroid in the process.

Parenchymatous, gummatous, or suppurative iritis affects the stroma of the organ, whose cellular and vascular elements then proliferate, causing a regular or irregular increase in its dimensions. The attachments which form between the lens and iris are firm and unyielding. Tubercles, nodules, or "condylomata" (gummata), become visible as light- or dark-colored, circumscribed elevations on the surface of the iris, marginal or not in situation, sometimes vascularized as they persist, and attesting the unicity of the syphilitic process in all tissues of the body. Pus may form in the anterior chamber, especially in cachectic subjects.

The diagnosis of these disorders is not difficult, since their association with a syphiloderm, often papular, and the history of the case, usually corroborate the suspicion aroused by the lachrymation, pain, photophobia, and circumcorneal vascularization. The treatment is by the administration of mercury and the iodide of potassium internally, pushed until the system is controlled by these drugs; and by the instillation into the eye of the sulphate of atropine in solution (grs. ij. ad f ℥ j. [0.133–32]). In exceptional cases vesication over the temple may be employed with advantage, or a leech or two affixed near the ear. Opium hypodermatically, or cocaine locally, may be required to relieve pain. The oleate of mercury and morphine also may be applied by inunction over the brow, even where the mydriatic is employed. The eyes should be disused and protected against light (by a darkened chamber or shaded glasses). Paracentesis of the cornea and iridectomy may be required in severe cases at the hands of the ophthalmic surgeon.

A form of iritis has been observed in the first half-year of life of infants, mostly of the female sex, affected with inherited syphilis. It is both unilateral and bilateral, and accompanied by few of the marked subjective symptoms of the disease experienced by adults, but is far more liable to result in pupillary occlusion.

The *lens* is affected in syphilis chiefly by extension to it of inflammation of the delicate organs with which it sustains anatomical relations. Cyclitis, or inflammation of the ciliary body, is for the most part similarly excited by an iritis or choroiditis of the same eye. Very rarely, indeed, a gummatous exudation occurs primarily in its substance, and then commonly the iris is secondarily involved, with characteristic symptoms.

Choroiditis and Retinitis.—Plastic, serous, and parenchymatous inflammations of the retina and choroid are described by authors, the distinction between which forms, as also between inflammations of the two organs, is difficult to establish. The objective symptoms of these disorders, as recognized by the aid of the ophthalmoscope may be described as increased vascularity, ecchymosis, opacity, œdema, and appearance in the fundus of the eye of whitish or yellowish spots. Often the pigment of the choroid atrophies, permitting in one or more places a view of the sclera through its tissue. Blackish areolæ may surround these irregularly bordered macules. In other cases the choroid presents the appearance of maceration; or again, circumscribed nodules (gummata) project above the general level. When there are distinct retinal changes, the point of entrance of the optic nerve is usually pinkish or reddish in shade, œdematous, and surrounded by distended and conspicuous vessels; or hidden from view by plastic deposits upon its surface, or by a fog in the vitreous humor.

The *optic nerve*, when affected with syphilis, is usually involved after extension to it of a retinitis or choroiditis. It is said also to be very rarely primarily infiltrated with a gummatous product. The same is true of the vitreous, which is usually implicated only after syphilitic changes in its investing membranes.

Paralysis of the nerves of the eye is as nearly pathognomonic of syphilis as is iritis, from fifty to sixty per cent. of all cases occurring in syphilitic subjects. Many of these are early phenomena of cerebral syphilis, and hence amblyopia, failure of co-ordination of the ocular movements, and visual disturbances of every kind should be closely investigated at all times when occurring in the victim of syphilis. Paralysis of the third pair of cerebral nerves, the oculo-motorius, is characterized by ptosis of the upper lid, external strabismus, and inability to move the globe upward, downward, or inward. Accommodation is wholly or partially lost, and the pupil is dilated. Paralysis of the sixth pair, the abducens, is, on the other hand, characterized by internal strabismus, amblyopia on the outer side of the vertical axis of the eye, and inability to move the globe outward. Paralysis of the fourth pair, the patheticus, is characterized by amblyopia for all objects lying below the equator of the globe of the eye, and an effort on the part of the patient to correct the visual impressions of objects below that equator by the inclination of the head.

These paralyses may occur singly or in combination; and, with or without them, may be recognized monocular mydriasis, which, albeit occasionally associated with grave cerebral syphilis, the author has seen persist for a year without impairment of co-ordination or other ocular symptom. Unquestionably these paralyses may be due at times to gummatous and other syphilitic changes in the membranes, periosteum, and bones within the cranial vault. Convergent strabismus is readily distinguished from paralysis of the sixth pair by the relief of the squint in the former case when the sound eye is covered. The treatment of these paralyses by the usual method of managing constitutional syphilis is, for the most part, encouraging. Tenotomy may be occasionally required.

The Eye in Inherited Syphilis.—In congenital disease the lids, conjunctivæ, cornea, iris, choroid, retina, and optic nerve, may, one or all, be affected with specific inflammatory changes, or, more commonly, by gummatous deposits resulting in degeneration and ulceration. Grave ocular troubles in early life, especially if coexisting with persistent alterations of the subcutaneous structures, periosteum, or bone, should generally awaken the suspicion of syphilitic disease.

Affections of the Ear in Syphilis.—The external ear may exhibit the lesions of secondary syphilis. Mucous patches, erosions, ulcerations, and the pathological secretions furnished by them, are occasionally sources of

annoyance in the external auditory canal. The underlying submucous tissue, cartilages, and bones may become also the seat of gummata capable of resolution under treatment; and, on the other hand, of degeneration with the production of ulcers. Nodes also form, which are at times of such size as to block up the lumen of the canal and interfere with audition. The middle ear is, more frequently than the external canal, implicated in syphilis, because of its anatomical relations with the nares and fauces But little is known of these complications. Undoubtedly mucous patches, with erosive and ulcerative sequelæ, occasionally form upon the mucous lining of the Eustachian tube or lining membrane of the middle ear. There is usually considerable pain in the latter event; the drum membrane loses its polish; its surface may become the seat of vascularized deposits; or it may be perforated; as a result the ossicles may be loosened or lost, and the mastoid process or other osseous tissue in the neighborhood become carious. Presumably also, nodes may spring, in rare cases, from the bony tissue beneath the investments of all parts of the middle ear; and undoubtedly, if recognized in life, these would explain many obscure cases of deafness. The changes in the internal ear due to syphilis are so obscure as to furnish no basis for study.

Under the heading "Sudden Deafness Produced by Syphilis," Bumstead and Taylor describe a condition in which, after manifest hyperæmia of the drums, both ears are affected suddenly with an extreme degree of deafness accompanied by vertigo, and without obvious changes in any special part of the organ of hearing. In these instances the cochlea and labyrinth have been supposed to be the seat of disease; yet other cases have been explained by disarrangement of the ossicles. Deafness may, however, be due to syphilitic involvement of the brain; and, in this relation, is more common than is generally supposed. (See also Syphilis of the Ear, in the Appendix.)

Aural Affections of Hereditary Syphilis.—Severe, and often remediless, loss of hearing, usually involving both ears, may occur in the subjects of syphilis in the second decade of life. According to Hutchinson, the result depends upon changes either in the auditory nerve or in the deeper parts of the organ of hearing, more particularly the labyrinth. The loss of hearing may be complete and result in deaf-mutism.

Affections of the Respiratory Tract. *The Nose.*—The lining membrane of the nares may be the seat of macules, papules, erosions, mucous patches, and ulcerations, with catarrhal symptoms, the discharge from the nares becoming serous, purulent, or hæmorrhagic. Inspissated masses of these secretions smeared with an offensive discharge are at times expelled. Gummata form in the same region, whose degeneration leads to ulcerative changes in cartilage, periosteum, and bone. This order of sequence may be reversed, the gummatous infiltration first occurring in the osseous structure. The septum, floor, Eustachian tube, pharynx, roof of the mouth, antrum, and even the cerebral meninges, may be attacked by extension of the disease from one point to another. When the bridge of the nose is in this way undermined, a characteristic and highly disfiguring flattening occurs, which is rarely seen in any other disorder save syphilis, traumatism excepted. Cartilaginous destruction is productive of flattening of the tip of the nose. The practically remediless nature of these deformities renders the treatment of all nasal disorders in syphilis a matter of the highest consequence. When the antrum of Highmore is affected there is a peculiar tumefaction, unaccompanied by coloration or change in the skin, of one side of the face, whose treatment may require removal of a tooth, penetration of the floor of the antrum, and the wearing of an obturator for a time. When the Eustachian tube is involved, the drum membrane may be perforated and a purulent otitis media become apparent. Many of these changes, whether vegetative, erosive, or ulcerative in type, are accompanied by fetid ozæna, nasal phonation, and partial or total loss of the olfactory sense. Sometimes osseous fragments, varying in size from a hemp-seed to a finger-nail, are discharged from the nares, the detritus of the carious process as it affects the nasal, turbinated, or other bones. Eburnation and thickening of the bones *in situ* may also result. The internal treatment of these cases is by mercury, iodide of potassium, the mineral acids, and ferruginous tonics. Locally the treatment may be successfully conducted by the aid of mercurial fumigation, but the use of a cleansing douche, followed by lotions containing the bichloride of mercury, resorcin, iodized phenol, potassium chlorate, or boric acid, may be regarded to-day as preferable.

The Larynx.—The vocal cords, arytenoid and glosso-epiglottic folds, and all parts of the mucous, submucous, cartilaginous, and osseous tissue of the larynx, may become the seat of syphilitic changes. Diffuse circumscribed erythema, mucous patches, papules, "condylomata," vegetations, erosions, and gummata may be followed by superficial or deep ulcerations, circumscribed or extensive infiltrations, and cicatrices whose contraction may induce grave and dangerous laryngeal stenosis. Pain, cough, changes in the volume or pitch of the voice, dyspnœa and dysphagia, are not at first noticeable. The supervention of œdema may gradually or rapidly usher in a serious condition. Later, when stenosis of the larynx (the more frequent of the ultimate results) is induced by cicatricial contraction, or (more rarely) by vegetations, false membranes, gummata, or nodes, the voice may be reduced to a whisper or there may be complete aphonia, dysphagia to a slight extent, or dyspnœa even to a grade demanding tracheotomy for the preservation of life. The mucous membrane of the larynx is affected also with a chronic form of infiltration which results in a characteristic induration of the important submucous tissues of the larynx, distinguishable from œdema by its firmness and density. The deeper ulcerations of this organ resulting from degenerating gummata, circumscribed or diffuse in extent, commonly spread from similar lesions in the pharynx, resulting ultimately in destruction of the epiglottis, leaving often in such cases a single wide and ragged laryngo-pharyngeal chasm; or involving the cords, aryteno-epiglottic ligaments, and deeper structures. When the cartilage is involved, crepitation is said to be perceptible after the occurrence of perichondritis; and sequestra have been removed when caries or necrosis has attacked the ossified cartilage. Syphilitic aphonia, obscure as to its immediate cause, as well as paralyses whether of one or both sides, are not to be confounded with syphilitic aphasia. Tuberculosis can now be satisfactorily differentiated from these affections by the modern methods of recognizing the bacillus of that disorder, as well as by the other signs of phthisis and the absence of a history of syphilis and its concomitant symptoms.

The *trachea* may become the seat of lesions similar to those recognized in the larynx; but the absence here of the delicate mechanism required for phonation explains why they are rarer, less conspicuous, and less complicated. The larynx, trachea, and bronchi are usually simultaneously or successively involved, the trachea alone very rarely. All the lesions of mucous surfaces in syphilis, all the vegetations, infiltrations, and degenerations, may here be noted, including extra-tracheal abscess from perforation. Stenosis from cicatricial contraction may here also induce fatal results. The internal treatment of laryngeal and tracheal syphilis is that of the disease in general. Locally, the parts may be sponged with solutions of boric acid, benzoin tincture, eucalyptol, or dusted with iodoform, or tannin in fine powder, reduced if desired. The galvano-cautery is best employed in the surgical management of membranoid occlusions, which are, it should be remembered, quite uninfluenced by large doses of the potassic iodide. The last-named drug is indeed, in some cases, credited with producing a form of laryngeal œdema. Dilatation with bougies has not won for itself much favor in the management of these cases. The use of tobacco, both by smoking and chewing, is to be interdicted in all cases.

The *bronchi*, it can scarcely be questioned, may become the seat of the syphilitic changes described in con-

nection with the larynx and trachea. Few cases, however, have been carefully studied, though stenosis following ulceration has been recognized post mortem.

The *lungs* may be the seat of a syphilitic infiltration affecting usually one side of the chest only, and then the upper, middle, or lower lobe. The pulmonary tissue becomes so dense in these cases as to be impermeable to the air; and yellowish points are visible here and there in the relatively small patch of consolidation, due to the irritation of the parenchyma by the sclerotic nodule.

These sclerosed portions of the lung by their contraction induce either stenosis or ectasia of the normal canals and chambers in the vicinage. Under the microscope the sclerosis is seen to be made up of bundles of firm connective tissue, between which appear stellate, fusiform, and roundish cells, with a granular detritus. The vessels of the part are first engorged with blood, and later choked with the stasis of their contents.

Pulmonary gummata, or circumscribed syphilomata, of the lung rarely form at the apices of these organs, but are found in all other parts. They are grayish, semi-solid masses, varying from the size of a pea to that of an egg, set in the pulmonary parenchyma, surrounded always by an opalescent, fibrous, basket-like capsule, and as they grow older often exhibit one or more yellowish points in their mass where caseation has begun. Softening in these progresses from centre to periphery, and the contents may find exit by the portal of a neighboring bronchus with a secreting cavity left behind; or resorption may occur with the result of leaving a fibrous mass in the lung tissue, having a cheesy centre. These conditions may be found in one and the same lung, gummata forming in cavities left by others that have degenerated, fibrous sequelæ of resorption, and contracting cicatrices. Often the pleura and bronchi are either involved in the same process or exhibit the irritating effects of the pulmonary neoplasms. Microscopically, the centre of these gummata is found to be made up of granular connective tissue, in process of degeneration, and highly refractive granules. The fibrous tissue is concentrically wrapped about them, the cellular elements nearest the core having often undergone in part fatty metamorphosis. Still more externally lie irregular masses representing a small-celled infiltration, which in places blocks up the alveoli. The symptoms of these lung-changes of syphilis are largely those of non-specific inflammatory disorders, viz., bronchial catarrh with expectoration of muco-pus; diminution of sonority in percussion; limitation of the respiratory area in affected parts of the lung; dry and moist râles; prolonged expiration; and dyspnœa. The author has published a report of a case of severe hæmorrhage in a patient affected with syphilitic pulmonary sclerosis, with complete recovery after appropriate therapy. In the event of degenerating gummata of the lung, the symptoms are those of pulmonary caverns, whatever be the cause, hollow gurgling râles, pectoriloquy, raucous voice, etc. The diagnosis is established by the history of syphilis and any concomitant symptoms present; by the relative immunity of the pulmonary apex; by the smaller number and larger size of gummata, as contrasted with miliary tubercles; and by the absence of the bacilli of tuberculosis, of the signs of hydatid cysts, and of neoplasms of other diseases. The treatment is that of syphilis in general, with such remedies as are specially indicated by the pulmonary symptoms present.

Affections of the Digestive Tract. *The Mouth.*—As the lining membrane of the mouth is more often exposed to the eye of the practitioner than any other mucous surface in the body, the symptoms it exhibits in the victim of syphilis may be regarded as representative of mucous lesions in general. They are all properly in alignment with the cutaneous lesions, the modifying influences being chiefly heat, moisture, and motion; the latter incidental to the performance of the important functions of the mucous cavities. Thus the buccal cavity is often the seat of diffuse or circumscribed erythema, in dull red shades, faucial or palatal in situation, with defined or irregular outlines, accompanied by infiltration, œdema, and often by erosions. These may be multiple, pea-sized patches, or a single sheet of diffuse blush. The former, after maceration, may, by either a vegetative or a degenerative process, form papules, mucous patches, or ulcers. In malignant cases a dull-red erythema often precedes the gangrenous crateriform ulcer which opens, almost as at a stroke, the oral and nasal cavities by a communicating chasm.

Mucous Patches (Mucous tubercles, plaques muqueuses, moist papules, etc.).—The larger number of these lesions appear in the mouth and about the anus, though they are to be seen near all the mucous outlets of the body. They are far more common and more severe in the mouth of men than of women, on account of the tobacco habits of the former. They are early and late lesions of syphilis, and are represented in the symptoms of relatively few diseases not syphilitic. They consist of roundish, ovalish, or irregularly shaped disks, or longer, narrow, indefinitely outlined bands of a delicate rosy hue; grayish or opalescent in color; often granular and elevated about a millimetre above the general level of the surface where they appear. Many of them look as if covered with a delicate pellicle. When of a pinkish or reddish shade, they represent merely a stage of hyperæmia of the membrane; when opalescent, as if pencilled by the silver crayon, a stage of maceration of the previously infiltrated epidermis; when granular, a stage of attempted repair, the loosened pellicle having been removed by friction or otherwise, and the surface beneath forming a new epithelial envelope. They may form upon a chancre when undergoing its so-called "transformation *in situ*," already described. When located in quasi-mucous situations, viz., those portions of the skin in the vicinity of the mucous outlets subjected to friction and kept moist and warm (inner faces of the thighs, inside of the toes, etc.), they may vegetate and produce the condyloma, a lesion frequently seen about the anus and genital region, more particularly in syphilitic women of filthy habits. These are usually circumscribed, multiple, roundish, or irregularly shaped, wart-like elevations, smeared with a whitish mucus, highly contagious, and of especially disgusting odor when seated about the ano-genital orifices. In the same situation they are remarkable for the production of a sensation of itching, rarely awakened by other syphilitic lesions. Occasionally they are dry. They are, as a matter of fact, merely papular lesions, flattened by apposition of the surfaces between which they are developed, or vegetating as the clefts in these same surfaces permit of such a growth, secreting because moist and macerated, and itching because irritated by the same agencies. When exposed, as about the bearded lips and nares, they are dryer, and browner, or duller red in hue. They occur in and about all the mucous outlets, and affect all mucous surfaces, with a marked predilection for the neighborhood of the muco-cutaneous borders. They are exceedingly common in both infantile and inherited syphilis. They may become cracked, eroded, and superficially or very deeply ulcerated. Their excessive proliferation produces enormous masses of secreting, wart-like, softish growths, described by authors as frambœsioid condylomatous syphilodermata.

The mucous patches of the mouth are less elevated and more opalescent than others, and appear upon the inside of the lips and cheeks, gums, uvula, palate, tonsils, and pharynx. They should never be confounded with the transitory, minute, usually distinctly circular, aphthous ulcerations to be seen in healthy adults after a fit of indigestion; nor with the persistent, much firmer, leathery disks, or striated or ribbon-like streaks, described as psoriasis linguæ, leukoplakia buccalis, etc., which, as is now well known, may be the earliest epitheliomatous transformation of a mucous membrane; nor, lastly, with the so-called "smokers' patches" (plaques des fumeurs, etc.), which in many cases, it can scarcely be questioned, represent buccal lesions in a veteran of syphilis.

The tongue may display a wide variety in the lesions of syphilis. In the order of gravity may be named: Multiple, macular lesions, the size of a pin-head, abundantly spread over its upper surface; mucous patches in all

forms, particularly over the edges and tip, often forming where the organ is rasped by the rough edge of a carious molar tooth; flat, circular papules, the size of a bean and larger, elevated a millimetre or two above the general level; circumscribed and diffuse, superficial or deep (parenchymatous) scleroses, usually developed upon the upper surface of the organ and near its mesian line, characterized by irregular increase of bulk and almost cartilaginous density, which may result in resorption and atrophy or ulceration; and, lastly, superficial or parenchymatous gummata, submucous or muscular in site, occasionally single, often multiple, which also may disappear by resorption or degenerate by ulceration. One of the remarkable features of disintegrating syphilitic, as distinguished from other neoplasms, of the tongue is the relatively slight damage apparent after completion of repair. The author lately examined a patient's tongue two years after closure of a crater, the size of a pigeon's-egg, left by a deep gumma, with the result of finding merely an irregular band-like scar to indicate the site of the lesion. These all are to be distinguished from epitheliomata, which are more voluminous, more hæmorrhagic, less deeply excavated, more irregular in mass, and more painful; as also from colloid lingual tumors (so-called "hygroma" of English authors), with the appearance of vesicles on the upper surface and enormous asymmetrical increase in the bulk of the organ in childhood; and, lastly, from tuberculosis of the organ, rare of occurrence, to be recognized only by its histological characters.

The *maxillary bones* may undergo necrosis as a result of syphilis. The most common site of the accident is the central part of the dome of the hard palate. There is first a dull-red erythematous swelling of the membrane and submucous tissue, which in severe cases may seem to melt away like wet paper, leaving a conical perforation through which communication is opened between the oral and nasal cavities; in other cases an abscess forms and bursts, after which the bone is laid bare and exfoliates in larger or smaller masses from time to time. Necrosis of the alveolar processes usually occurs in the upper jaw. Gummata of the soft palate often form insidiously; are circumscribed or diffuse; at first firm, later softish, tumors, varying from the size of a pea to that of a small nut, or in patches of thickening. Absorption or ulceration may result, and the latter often rapidly, in consequence of the lax and unsupported tissues involved; the process in grave cases opens (by destruction in whole or in part, of the uvula, pillars of the fauces, and velum) a wide chasm between the fauces and the posterior nares. Interference with the Eustachian tube often produces temporary deafness. The voice is disagreeably nasal, deglutition is often difficult in the erect posture (patients with extensive tissue-loss will often assume singular postures, by which they can even succeed in swallowing liquids without the passage of the latter into the nose), and the pain in general is quite disproportionate to the severity of the damage. Marvellous are the reparative results when, as is usually the case under sound management, repair ensues. The remaining fragments of the velum palati contract adhesions to the posterior pharyngeal wall, the chasm contracts, and the expert can trace the picture of the mischief that has occurred when inspecting only the narrow and distorted chink left after contracture is complete.

Fournier only has reported a case of syphilitic involvement of the sublingual gland.

The *pharynx* may become the seat of macules, papules, mucous patches, gummata, and ulcers, which in many cases are formidable. The latter may spread from the posterior nares and extend downward into the œsophagus, or backward, so as to produce destructive effects upon the periosteum of the vertebræ and the structures they protect. Occasionally, patients long neglected or badly treated exhibit gigantic caverns, including what were once the nasal, buccal, and pharyngeal cavities, the whole lined with a granulating or secreting, and ulcerated membrane. Even in those extreme cases where one is disposed to wonder even at the prolongation of life, repair ensues and emphasizes the striking, almost pathognomonic, distinction between the damages inflicted by syphilis and all other destructive diseases.

The *œsophagus* is said to be very rarely the seat of syphilitic lesions which, after ulceration, may produce stricture, either spasmodic or organic, resulting in serious danger to life.

The *treatment* of all these lesions is practically the same. Internally, mercury and the iodide of potassium are essential, the latter often in the largest permissible doses, to save important organs. Care of the patient's nutrition is in most cases imperative. Locally, the nitrate of silver, sulphate of copper, chlorate of potash, tannin, resorcin, acid nitrate of mercury, nitric acid, and tincture of iodine, may be employed in strength varying according to the requirements of each case—the first-named in solid stick or solution of a strength of from five to sixty grains to the ounce (0.33–4. to 32.0). By spraying, pencilling, dusting, washing, and gargling, these preparations may be used, with the greatest advantage, a number of times throughout the course of the day. The following are excellent formulæ for gargles:

℞.	Potass. chlorat.	ʒ j.	4.
	Mel. despum.,		
	Myrrh. tinct	āā f ℥ ss.	16.
	Aq. dest.	ad f ℥ iv.	128.

M. S.—Gargle. Use diluted as required.

℞.	Potass. chlorat.	ʒ j.	4.
	Infus. lini.	O j.	500.

[Bumstead and Taylor.]

℞.	Acid. carbolici.	ʒ j.	4.
	Glycerin,		
	Spts. vin. rectif.	āā f ʒ ij.	8.
	Iodin. tinct	f ʒ ss.	2.
	Aq. dest.	ad f ℥ j.	32.

M. Five to fifteen drops in a third of a tumbler of water for gargle or lotion.

The tooth-brush, in all cases, is to be regularly employed twice daily; if the patient is unaccustomed to its use the mouth should be well cleansed and the gums rubbed with a bit of soft muslin on the finger, dipped in water to which a few drops of the tincture of myrrh and cinchona has been added. Tobacco is to be, in every form, absolutely interdicted; and all very hot and very cold, and irritating articles of diet are to be excluded (*e.g.*, hot coffee, ice cream, vinegar, spirits, spices, etc.).

The *stomach and intestinal canal* may become the seat of syphilitic lesions of the type seen upon the other mucous surfaces. Huet, Cornil, Klebs, and others report gummata of this part of the digestive tract; Leudet, Virchow, and Fauvel describe diffuse infiltrations of portions of the tube; Engel, Fioupe, Cullerier, and others, perforating ulcers (probably due to gummata) as well as scleroses resulting in contracture, even productive of sufficient irritation to light up a peritonitis near a stricture of the colon. It should not be forgotten that a long list of functional disorders of the alimentary canal might be enumerated as of occurrence in the syphilitic subject, which are often due to the toxic influence of the disease (cachexia, etc.); to the effect of certain of the medicaments ingested or externally applied for its relief; and to improper alimentation or hygiene.

The *rectum* may become the seat of a series of important changes due to syphilis. Women are more liable to be thus affected than men in the proportion of eight to one, a preponderance which has been referred to the anatomical differences between the sexes; to the physiological fluxes of women; previous pregnancies; and to unnatural or excessive coitus. Chancroids, occurring as they do frequently about the anus of women, may result in induration of the submucous tissues, accompanied by purulent and sanguinolent discharges, constipation, or looseness of the bowels, and painful defecation. This condition is to be carefully distinguished from syphilitic stricture of the rectum.

The syphilitic affections of the rectum may, perhaps, include the category of syphilitic lesions of mucous surfaces in general. The most important, however, are

those characterized by ulceration or gummatous changes. The former may extend from without inward, from the perianal region to an inch or more within the sphincter; or may begin by one or several points of ulceration in the latter situation. The so-called "ano-rectal syphiloma" is a cylindriform, gummatous, non-ulcerated infiltration of the entire circumference of the ano-rectal walls, capable of producing stricture by transformation into fibrous tissue. It is, however, an error to suppose that stricture of the rectum not due to chancroids, but syphilitic in character, always conforms in type to the syphiloma. The author has at present under his care a middle-aged woman, whose husband and two children are victims of severe syphilis, and whose left lower extremity is extensively seamed with perfectly typical syphilitic cicatrices. There are in this case four abscesses in the nates, communicating by fistulous sinuses with the bowel and vagina, the syphilitic stricture of the rectum being represented by a sharply defined, thin, annular coarctation of the rectal wall, with a submucous gummatous infiltration strictly limited to the ring of the coarctation. It is evident that only in exceptional cases, probably during the period before contracture has set in, can internal medication accomplish practical results in these cases. Dilatation, or division of the stricture by the knife or galvano-cautery, is usually required, with free opening of all abscesses and sinuses, and observance of strictest antiseptic precautions with bichloride dressing. The future is, however, rarely promising for these cases, many women who are the victims of the disorder having their health profoundly impaired by previous suffering and disease.

The *liver*, like the intestinal canal, may suffer during the period of syphilis by functional disorders, which may depend upon slight structural changes participating in the process which results in the cutaneous exanthem. The icterus probably originating in this way, which may somewhat precede or accompany the first syphiloderm, has already been described. It may be accompanied by hepatic congestion and by symptoms of malaise, hebetude, cephalalgia, and even slight pyrexia. The tertiary forms of syphilitic involvement of the liver are well marked. General, more commonly partial, interstitial hepatitis, affecting chiefly the capsular and ligamentous attachments of the organ, produces a distortion of the gland by contracture of fibrous bundles which, springing from these attachments, penetrate the hepatic parenchyma and divide it into uneven lobulations and irregular masses separated by furrows. There is at first increase, and later diminution, in the bulk of the organ, with the usual symptoms of cirrhosis. Hepatic gummata are of more frequent occurrence, and in "galloping" cases may be seen within six months after infection. They are usually grouped in clusters of from six to a dozen lesions, varying in size from a large pin-head to a small nut. Centrally they contain roundish cells and granules in a delicate connective-tissue reticulum, surrounded by a fibrous envelope, and embedded in dense hepatic tissue. The symptoms in mild cases are probably scarcely sufficient to indicate the nature of the affection. In others, disturbance of the alimentary canal (icterus, constipation, dysentery); pain in various degrees, limited to the hepatic region or radiating from it; and, very rarely, morbid changes perceptible on palpation of the enlarged, or previously enlarged and subsequently shrunken, organ, may first point to the precise nature of the trouble.

Gummata of the liver are to be distinguished from hydatid cysts; carcinoma (of advanced years); hepatic abscess (in persons who have been long resident in tropical countries); tubercles (usually softer, more cheesy, more purulent in the centre); and the rare forms of sarcoma of the liver. The prognosis of hepatic syphilis is usually not grave.

Amyloid degeneration of the liver may be the result of syphilis as of other diseases. There is increase in the bulk of the waxy-looking organ, the hepatic cells becoming enlarged after involvement of the swollen hepatic capillaries. Often there are coincident amyloid changes in the heart and spleen. The symptoms of hepatic gummata are as obscure in many cases as in syphilitic cirrhosis. There may be ascites, hæmorrhage from the portal vein, and dyspnœa. The treatment is largely that of syphilis in general.

The *spleen* often enlarges in those early periods of syphilis when the lymphatic glands tumefy. Commonly the enlargement subsides as the disease progresses or is modified by treatment. Syphilomata of the spleen (gummata) are rarely observed, but have been recognized in both circumscribed and diffuse forms. Splenic gummata are yellowish, softish nodules, from the size of a pin-head to that of a small nut, set in a dense splenic tissue of unusual dryness. In diffuse forms, the organ appears to be in part hypertrophied and dark brown in color. Later, islets of grayish sclerosed tissue become apparent in this mass, whose involution leaves cicatriform depressions. There is reason to believe that rarely a perisplenitis may be lighted up by these changes, leading to the formation of whitish patches of almost cartilaginous density. The clinical symptoms of syphilis of the spleen are obscure.

The *pancreas* is said to be occasionally the seat of changes which have been supposed to represent the circumscribed and diffuse syphilomata recognized in the liver and spleen.

AFFECTIONS OF THE CIRCULATORY ORGANS.—*Myocarditis*, recognized chiefly in post-mortem examinations, may be a late complication of syphilis, which affects men more often than women in the proportion of six to one. Softish, yellowish gummata, from the size of a nut to that of an egg, as well as circumscribed and diffuse sclerosis, have been recognized in the ventricular walls and auricles of both sides. Plastic or fibrous metamorphosis of the muscular tissue about any of these lesions may occur. Whitish diffuse infiltrations, firm, or of the consistence of a sarcoma, with round-celled infiltrations and vegetations, may affect the endocardium or muscular tissue; and the same changes in the pericardium may result in partial or total obliteration of its sac. These commonly originate in sub-endocardial or sub-pericardial gummata. Wagner, Lancereaux, and a few others have reported gummata limited to these serous membranes. The symptoms excited by these changes are dyspnœa, palpitations, cyanosis, præcordial distress, and angina pectoris. The prognosis is naturally described as grave, since all the identified instances of this affection were recognized in the bodies of the dead. It is reasonable, however, to suppose that syphilis here, as elsewhere, exhibits its usual amenability to treatment in the case of patients with symptoms not diagnosticated in life.

Arteries and Veins.—The femoral, jugular, saphena, and other veins have been reported affected with a phlebitis due usually to the pressure exercised by a gummatous tumor in the vicinity. A sclerous phlebitis, in which the intima was first attacked, has also been recognized post mortem.

The capillaries and arteries also may be primarily or secondarily involved. In the latter case it is commonly the result of compressive or destructive effects exerted by syphilitic processes in adjacent organs. Syphilitic endarteritis, however, is much more common; and recent investigators, including Virchow, Heubner, and others, have revealed its pathology with sufficient clearness. These lesions are more commonly observed in the smaller cerebral arteries, but the carotids and other vessels are occasionally involved. The definite limitation of the disease to a single patch is declared by the rapid appearance of whitish, opaque nodules, the size of a millet-seed, composed of small, roundish, or spindle-shaped cells, which may be agglomerated into a firm, fibrous mass, from the size of a pea to that of a nut, obliterating the lumen of the invaded artery by thickening of all its investing coats, and producing eventually either rupture or an atrophic or cicatriform relic of its existence. This infarction is remarkable for the indirect results it produces, including cephalalgic, aphasic, paretic, paraplegic, and even comatose, symptoms.

THE GENITO-URINARY ORGANS.—Secondary and tertiary, as well as primary, symptoms of syphilis are disclosed in the genito-urinary tract of patients of both sexes.

The *penis* may become, in one part or another, the seat of circumscribed tertiary syphilitic infiltrations, as well as of gummata.

Lesions of this nature may be subcutaneous, or there may be nut-sized masses deeply lodged in the substance of the corpora cavernosa, or in the submucous tissue of the urethra. Some of the lesions discovered post mortem, and described as "chancres of the deep urethra," are really tertiary ulcers resulting from broken-down gummata of the prostatic or membranous urethra. Jullien figures a cavern of the cutaneous surface of the penis originating in this way in one of Langlebert's patients. Bumstead and Taylor describe tubercles of syphilitic origin near the furrow at the base of the glans.

Any part of the *testicles* may be affected with syphilis. The *epididymis*, when involved, may display either an early or late form of syphilitic epididymitis.

The early form, first described by Dron, in 1863, may be observed at any time between the third and thirtieth months after infection. The disorder bears no relation to gonorrhœal epididymitis. The globus major, or head, of the organ, much more rarely the globus minor, is attacked and either insidiously or acutely affected, producing a roundish or squarish, circumscribed tumor, from the size of a bean to that of a small nut, which has been compared to a "monkey-nut screwed to the testicle." One or both organs may be involved, successively or simultaneously, and the globus minor may be attacked later. It is amenable to treatment, and commonly disappears without unfortunate sequelæ.

The late form is often connected with gummatous changes in the testis proper, but very rarely arises independently of the latter. Here also the globus major is more often attacked; and resolution, as is the case with tertiary deposits in the testis proper, may be followed by atrophic changes.

Syphilitic *orchitis*, sarcocele, or albuginitis, may be a late secondary or tertiary symptom of syphilis, involving one or both organs simultaneously or in succession. In these cases, the body of the testicle is involved, often without the production of pain, in a smooth, uniform, and firm swelling, which may be due in part to enlargement of the testicle, and in part to a moderate grade of hydrocele concealing the irregularities perceptible later in the body of the organ. In other cases, this body can be recognized by palpation as the seat of one or several masses, from the size of a pea to that of a small nut, which may be at first isolated and circumscribed, but later become fused into a solid, resisting mass having the general shape of the testicle, but often three or four times larger. Under energetic treatment, resolution of these masses is accomplished; but obliteration of the vasa deferentia and atrophy, or fatty, fibrous, cartilaginous, amylaceous, even osseous metamorphosis of the parenchymatous tissue of the gland, may follow the absorption of the neoplasm. In this way the testicle may be, after completion of this cycle of changes, represented by merely a bean-sized mass of fibrous tissue. Suppuration and ulceration of the tunics almost never result, though a few authors have reported a resulting "fungus of the testicle."

Pathologically studied, the glands are found to be the seat of vascularization and proliferation of connective tissue, resulting in the production of fibrous trabeculæ traversing the organ in various directions, but always attached to its thickened investments, resulting by contracture in compression and atrophy of the secreting cells of the tubules. In other cases, true, grayish or yellowish gummata are found in the testis, single or multiple, diffuse or circumscribed, from the size of a pin-head to that of a pigeon's egg, environed by fibrous capsular coats. These commonly disappear by absorption; even in the rare cases of disintegration and the formation of "fungus of the testis," recovery ensues under proper treatment.

All syphilitic lesions of the epididymis and testis are to be distinguished from the gonorrhœal, the cancerous, the sarcomatous, and the tubercular. The blennorrhagic affections of the epididymis are acute in type, painful, attack the tail of the organ by preference, and are usually preceded by an unequivocal history of urethritis and discharge. The neoplasms of cancer and sarcoma in the testicle are usually accompanied by inguinal adenopathy, severe pain, systemic cachexia, extensive damage to the parts affected, and proneness to disintegration. Tuberculosis is far more common in young men virgin of all venereal antecedents, usually with tuberculosis of the prostate gland and marked dysuria. Almost invariably the bacillus tuberculosis may be recognized in the secretion obtained by "milking" the prostate. The treatment internally is by the potassic iodide and mercury. Locally, suspension is to be recommended; hot fomentations for relief of pain when such exists; and applications of salves containing lead, mercury, belladonna, or opium. The oleate of mercury and morphine, mercurial plaster, white precipitate salve, or the compound iodine ointment, may be applied. Strapping, as employed for relief of gonorrhœal epididymitis, may be practised with advantage in some cases. The prognosis is not unfavorable as regards the health of the patient; but, after double syphilitic orchitis, the patient may have complete aspermatism. The *prostate gland, vasa deferentia, common ejaculatory ducts*, and *vesiculæ seminales* are all probably the seat at times of syphilitic changes, the characters of which are not known.

In women the *labium majus*, usually one, occasionally both, may be the seat of gummatous changes due to syphilis. These may be late and unique manifestations of the disease. Often nothing can be gathered in cases of this sort as to the history of syphilis, a not uncommon experience in the infected of that sex. The organ is found, when examined, to be wholly or in part the seat of a dense, smooth or irregularly lobulated, vertically disposed tumor, very closely resembling in size and external appearance the scrotum which contains a testicle affected with syphilitic orchitis. It is usually an exceedingly indolent affection, lasting for years, rarely occurring at the outset till three or four years have elapsed since infection. It is often diagnosticated as "elephantiasis" of the labium. Disintegration of the mass by ulceration is rare.

The *syphiloma of the vagina* is similar to the lesion described above in the date of its occurrence, its exceedingly indolent career, and its existence for months without a single coincident symptom of syphilis to substantiate the diagnosis. Many of these cases have been recorded, treated, described, and even illustrated as "lupus of the vagina," which disorder is even rarer than this exceedingly rare manifestation of syphilis. When recognized, the vagina is converted into a thickened cylinder of tissue infiltrated with gummatous material, which greatly restricts the distensibility of the vaginal walls. In some of these cases the finger can with great difficulty be introduced into a channel through which viable infants have been ushered into the world. Irregular projections of the inextensible vaginal membrane, club-shaped, knobbed, granular, eroded or ulcerated, represent points where the larger submucous gummata are undergoing extreme development or ulcerating. These lesions break down more frequently and more disastrously than is true of the gummatous metamorphoses of the labia. Occasionally the ostium vaginæ is converted into a vast gummatous ulcer, invading the vestibulum and even the urethra. In one very severe case, the author has seen the rectum participate in the change.

The neck and body of the *uterus* exhibit more rarely and to a much less marked degree similar changes; induration, tumefaction, erosion, and ulceration of the mucous lining are reported by authors.

The Fallopian Tubes and Ovaries.—Lancereaux and Lecorché, respectively, have reported instances of diffuse and gummatous changes in the ovaries. In the case reported by the first-named author, there were two egg-sized tumors with long diameters parallel with the broad ligament. Bouchard and Lepine, quoted by Jullien, describe a single case of syphilitic salpingitis.

The kidneys undergo changes both in early and late syphilis. The phosphates and chlorides may be unchanged in the urine; urea may be quantitatively in ex-

cess, and albumen occur in quantities as great as in Bright's disease. Fifteen years ago, the author had under observation a case of severe albuminuria following syphilitic changes in the kidney of a man who is to-day living and well. Ten years ago, the author had under observation a severe case of anasarca following marked albuminuria, the patient, a young man, losing for five days ten pounds by weight daily in the Turkish bath. When recovery was complete, the patient was examined, and two years ago found free from disease. Similar observations have been made by most experts. Glycosuria has appeared and disappeared under precisely similar circumstances in syphilitic subjects. By some authors, these several conditions are claimed to be the results simply of the cachexia which may affect syphilitic as well as non-syphilitic patients, producing thus the amyloid, waxy, and other metamorphoses recognized in other cases. Without denying the possibility of such accidents, the author calls special attention to the striking fact that some of these cases bear the special imprint of syphilis in this, that after the exhibition of alarming symptoms, a complete, rapid, and permanent recovery may ensue after energetic treatment by mercury and, more often, by the iodide of potassium.

Syphilitic sclerosis and gummata of the kidney are late lesions of syphilis, and of rare occurrence, the last named being decidedly the rarer of the two accidents. In the diffuse form of syphilitic nephritis, there is usually a cycle of vascularization and tumefaction of the cortical portion, followed by interstitial proliferation, attachment of capsule to cortex, and formation of irregular, small or large nodules and projections from the surface whose exterior gross appearances suggest the similar lobulations of the syphilitic testicle. In some places these undergo lardaceous, amyloid, and other degenerative changes resulting in cicatrices. Precisely as the seminiferous tubules of the testicle are choked and eventually reduced to atrophy, are the glomeruli and uriniferous tubules of the kidney compressed, their channels obliterated, and their functions arrested. Here and there, on section, yellowish points or streaks of fatty metamorphosis are visible upon a granular surface; or the totality of the organ may be changed to a dead whitish color.

Gummata of the kidney are developed in both the cortical and pyramidal portions. They are single or multiple, grayish or whitish, definitely circumscribed masses, from the size of a pin-head to that of a pigeon's egg, with a whitish or reddened and vascular, fibrous envelope like a capsule. The centre is firm or cheesy, according to the age of the gumma; and the body of the lesion is made up of elements derived by proliferation from the connective tissue of the renal stroma. The subjects of these several complications of syphilis may suffer from vague pains, changes in the eye, peritoneum, pleura, and nervous centres, as well as ascites, anasarca, lumbar pain, hæmaturia, and albuminuria. The prognosis is decidedly less grave than in non-specific renal affections of similar type.

THE NERVOUS SYSTEM.—Affections of the nervous system may be early or late symptoms of syphilis, and are commonly the results of morbid changes in contiguous structures, such as bone, vessel, or investing membrane. They are much more common in men, chiefly because of the greater tax levied upon that sex in the demand for physical and mental strain constantly made in business.

The literature of nervous syphilis, most of which has been contributed during the last decade, has been both voluminous and valuable. In the following paragraphs it will be possible merely to trace the outlines of the important advances which have been made in this special field. The clinical pictures presented may be briefly named as follows:

Headache, insomnia, and irregular performance of functions of many of the organs of the body (eye, ear, heart, muscle, liver), dependent upon nervous disturbance, are not infrequent in the early periods of syphilis. The headache of this stage of the disease is often persistent and obstinate. It may be frontal, temporal, or occipital in situation, and of the moderate grade from which few infected subjects are wholly exempt, or severe, with intense nocturnal exacerbation, eliciting groans from the sufferer. This distressing complication of the disease may endure for only a few days, or last for weeks or months, proving eventually a mere precursory symptom of cerebral syphilis. Jullien, with certain others of the French school, lays stress upon the return or exaggeration, at this time, of the nervous symptoms displayed previous to infection by the subjects of hysteria, alcoholism, other cerebral affections, and epilepsy. Mild nervous manifestations are recorded by observers in this connection, including anæsthesia, analgesia, circumscribed hyperidrosis, and hypertrichosis, and cutaneous sensations of coolness, heat, formication, and tingling. Many of these features are such that the pathological changes on which they depend are necessarily unknown, or can be estimated only by reasoning from analogy. The supposed cerebral syphilis *sine materia* has for its basis only the non-recognition of structural changes where autopsies were made after the exhibition of well-marked nervous symptoms. In such cases, the possibility that the actual physical basis of the morbid phenomena was simply not discovered cannot be properly ignored.

When a patient is actually affected with *cerebral syphilis*, the unmistakable features of the accident often follow, as indicated above, the milder symptoms. The headache, which was at first simply annoying or tolerable, sets in with paroxysms of distress which make the patient dread the hours of the night as a period of torture. Constant or intermittent grinding, boring, or hammering sensations are referred to the whole or any one of the regions of the head described above. The patient will grow eloquent in declaring that the head feels as if it were screwed in a vice, riveted with iron bands, hammered upon an anvil, etc. Under treatment even this condition may yield in a few days, or, defying all skill (a rare complication), go on to the extreme conditions described later. At times definitely circumscribed regions of tenderness may be appreciated by both patient and physician, the latter by the pain evoked in percussion of the cranial vault. Insomnia, vertigo, intellectual hebetude, apathy, melancholia, and other morbid mental states, photophobia, and marked cachexia, are the usual concomitants of this state. When the disorder progresses uninterruptedly to full evolution, the patient becomes weaker, takes to the bed day and night, may exhibit some mild ataxic or paretic symptoms, usually goes into delirium, and presents the picture of one affected with utterly hopeless cerebral disease. Yet here, as so often in the history of this singular malady, he is really far from such a hopeless state, and thus furnishes the diagnostician with a clue to the syphilitic origin of the disease. Such a patient, properly treated, may rise from his bed, regain his flesh, return to his occupation, and live out his natural days, so far as regards the disorder under consideration.

Many odd features may be presented in the course of this complication. There are patients thus affected who present singular hallucinations; yet others suffer from vague terrors, dreading self-destruction or attacks from enemies.

Chorea, or at least choreic symptoms, may be recognized in some patients of this class. Spasmodic contractions may affect one or a group of muscles, either before or after the occurrence of paralytic symptoms, or independently of the latter. There may be slight, severe, transitory, remittent, or constant contractions of muscles of the head or extremities. One of the author's patients had a persistent, rhythmical swaying of the head from side to side, which lasted during the hours of wakefulness for a fortnight.

Aphasia, partial or complete, continuous or intermittent, may be the sole symptom of nervous syphilis, or occur before or after some of its grave complications. Often it is of sudden onset—one of the author's patients, for example, presenting himself at a bank in order to secure a foreign draft, and finding it on the instant impossible to make himself understood.

Paralysis, sensory or motor, partial or complete, usually succeeds a prodromal stage in which the patient has complained of obstinately persistent headache or some other premonitory symptom of cerebral disorder. The paralyses of the motor muscles of the eye belonging to this group of disorders have been already described. In a similar way the nerves of special sense, not only those of vision and hearing, but of olfaction and gustation, are totally or partially deprived of sensitiveness to external impressions.

Hemiplegia, occurring suddenly in a patient under fifty years of age, is, in the great majority of all cases, of syphilitic origin. It may be of early or late, sudden or gradual occurrence, and constitute a mere paresis of a group of muscles on one side, or much more rarely, a complete motor paralysis of one half of the body. It is usually preceded by cephalalgia, vertigo, lassitude, and neuralgia, with anæsthesia or tingling of the parts about to be affected, or mild choreic, rarely convulsive, seizures. Usually, after well-marked prodromal symptoms have been exhibited for some days or weeks, the patient awakes from sleep to find himself more or less unable to move one or both limbs of one side ; or the attack comes on in the hours of the day, the patient falling to the ground in a state of partial unconsciousness. The leg only is most commonly affected ; at times it is followed by involvement of the arm. Rarely the arm alone is affected. The bladder and rectum may participate in the resulting symptoms by loss of power to expel their contents. Alternate paralysis of the facial muscles is occasionally noted, *e.g.*, the right leg and the left side of the face. There may be dilatation of the pupil of the eye on the sound or affected side, with or without ptosis and involvement of the oculo-motorius. With these symptoms are occasionally associated total impotence, which may even survive the paralytic symptoms in the extremities, muscular tremors, and contractures. Sensory disturbances are few ; rarely there is complete sensorimotor loss. The affection is commonly attributed to an obliterating endarteritis. The prognosis in most cases is favorable.

Epilepsy is simulated in syphilis, under the influence of which epileptiform seizures occur. They are far rarer than hemiplegic complications. With or without premonitory sensations comparable to those experienced in the aura, both the *grand mal* and *petit mal* are represented in syphilitic seizures. There is, in the first case, the usual precursory severe cephalalgia, followed by distressing sensations in the extremities or about the heart, or singular creeping sensations of chilliness. Jullien insists that during these attacks the patient, even if unable to speak or to move, never wholly loses consciousness and never utters the cry, an important diagnostic distinction. The patient may fall as if shot, and exhibit tonic, followed by clonic, convulsions during a portion of the time, but rarely throughout the whole period occupied by a seizure. These convulsive movements do not notably affect all of the muscles of the body. The patient may foam at the mouth and bite the tongue or lips, though often, with marked convulsive seizures, these symptoms are absent. The intervals between these crises may be but a few hours, or days, or several weeks. They tend to multiply with each recurrence, and may result in dementia.

The *petit mal*, or mild form, is betrayed in tremors, spasms of the muscles, for example, of a single limb, or of the neck, or of one shoulder ; dyspnœa, dysphagia, or vertigo. Other patients experience sudden loss of memory, or imperception of environment, confusion of ideation, and incoherence of speech.

Paraplegia is, in more than fifty per cent. of all cases occurring in male patients under forty years of age, of syphilitic origin. Over ninety per cent. of cases of syphilitic paraplegia occur in males. There may be precedent cephalalgia of extreme violence, rachialgia, neuralgia, convulsive seizures of the muscles of the lower extremities, and hyperæsthesia or anæsthesia of the cutaneous surface. The paraplegia may be partial or complete, and sudden or gradual as to occurrence, but, as Althaus indicates, is unaccompanied by loss of consciousness, the patient often "assisting" at the invasion. It is apt to terminate in complete loss of power of both lower extremities, with and without sensory disturbances, partial paralysis of rectum and bladder, and complete impotence, lasting often for years. One side of the body may be involved after the other ; or the same side may be again affected after an interval of months has elapsed. Paralysis of cranial nerves, mental hebetude, mydriasis, and other signs of syphilis of the nervous system may be present, but are often absent ; and when the paraplegia is complete this may be the sole objective symptom of the infective disease.

The occurrence of *locomotor ataxia* in syphilis is both asserted and denied by observers. The author's experience is in accord with that of Messrs. Bumstead and Taylor, who are unable to recognize in the syphilitic affections of the cord, the well-defined sclerosis of the posterior columns which is characteristic of progressive spinal ataxia. The clinical symptoms of syphilitic changes in the cord may, for a brief time, simulate those of locomotor ataxia, but the results—not merely in well-treated, but in unrecognized and therefore wholly untreated cases of syphilis—are widely separated from the remediless sequelæ of the non-specific disease.

Fournier, Erb, and Althaus have advanced strong reasons in favor of the syphilitic origin of tabes, which have been offset by the statistical facts cited by Oppenheim and others. The classical features of the last-named disease are not only not exhibited by the syphilitic patient, but specific treatment, as even Fournier admits, has not succeeded in procuring relief for the ataxic "syphilitic" patient. Pathologically, it is known that syphilis rarely selects a definitely limited portion of the cord for its manifestations, but involves here and there a patch in the columns, near which can commonly be recognized altered vessels or investing membranes where the morbid process originated.

Symptoms resembling those of *general paralysis of the insane* (*délire de grandeurs*, etc.) have been recognized in a very few syphilitic patients (Dreer), but with relation to syphilis they may be relegated to much the same position as those observed in locomotor ataxia. There is a suggestive doubt as to whether the few patients affected with general paralysis, who have, at some remote period in the past, admitted the occurrence of "a chancre," really had syphilis, and as a result of this last-named disease the progressive symptoms of general paralysis.

Jullien aptly calls attention to the striking fact that the syphilitic patient supposed to have general paralysis is really ill (cachectic, anæmic, or adynamic), while the "real fool," on the contrary, exhibiting moral decrepitude, stupid facial expression, and perturbed cerebration, appears to be otherwise in good physical health. The former, moreover, is apt to display one or more of the syphilitic paralyses following a characteristic vertigo, hemicrania, or a cephalalgia, or some one of the ocular or aural complications of syphilis, in brief, at capriciously selected points where nervous symptoms are displayed. This also is associated with a milder exaltation of ideas, and a more rapid evolution of symptoms.

Other symptoms of nervous syphilis are exhibited in gastro-intestinal derangements (vomiting, etc.) ; functional disturbances of the kidneys and bladder ; and disorders of other viscera.

Coma, preceded by cephalalgia, anæsthesia, mental hebetude, or aphasic symptoms, may occur during sleep, or result from sudden diurnal accidents. The patient is usually found lying listless, or apparently asleep, pallid, expressionless, and not suffering pain. He may be roused to take food or drink, to thrust out the tongue, or even momentarily to recognize a friend or answer a question. The pupils are usually small, insensitive to the light, and covered by the lids. The globes are shrunken in the orbits. Sensibility and reflex excitability are either wholly preserved, impaired, or lost. The pulse and respiration are retarded in frequency ; the temperature is subnormal ; the excretions are passed unconsciously.

The pathology of these several complications of syphilis is explained chiefly in post-mortem examinations.

The cranial and other bones, when involved in an oste

itis or periosteitis (diffuse, circumscribed, gummatous), may produce nodes capable of explaining etiologically several of the groups of symptoms described above by pressure effects, including inflammation and even destruction of the parts invaded. Nodes of the internal tables of the cranial vault or of the vertebræ may thus be responsible for mental, paretic, paralytic, convulsive, neuralgic, and ataxic symptoms of the most varied character. The author is inclined to believe, after observation of typical cases, that well-defined cranial nodes in the outer table also of the skull are, as the result of sympathetic influences, capable of producing many of the milder symptoms of nervous syphilis.

The meninges of the brain (dura mater, arachnoid, pia mater) are subject to the same involvement. They may be changed by pressure of a node, and be agglutinated to it; or may be separately involved in diffuse or circumscribed, single or multiple thickenings, due to proliferation and vascularization of the tissues (pachymeningitis). The lesions may be symmetrical or asymmetrical, and involve the brain more often than the cord. These changes are capable in various degrees of producing cephalalgia; and at times a distinct area of meningeal surface may be recognized as the seat of the severe headache of syphilis, with intense nocturnal exacerbation, by pressure or percussion with the finger over a limited region of the skull —a manœuvre which decidedly increases the pain.

The brain and medulla are always involved as a sequence of changes either in the bones, meninges, or vessels in anatomical relation with those organs. The softening which results may be either of the red or white forms of ramollissement recognized in non-syphilitic cerebral disease. Gummata of the brain are recognized as single, or usually multiple, occasionally exceedingly numerous, circumscribed or diffuse, superficial or deep tumors, from the size of a millet-seed to that of a small egg. They most often exist as superficial lesions in direct association with gummatous changes in the meninges. They have a well-defined yellowish or whitish cheesy centre, with a firm, sclerotic, peripheral mass set in vascularized and greatly softened nervous tissue. Evidences of simple inflammation in the brain-substance, excited by the irritating presence of the neoplasm, are usually to be recognized, and are described by Jullien as distinctive marks of a cerebral syphiloma, inasmuch as the brain-substance tolerates with greater ease the softer nodules of tuberculosis. The deep-set lesions are much rarer, but are recognized, for example, in the substance of one ventricle, in the optic thalamus, the corpus striatum, or the white substance of the cord.

The arterial changes, responsible for so many of the nervous complications of syphilis, are of frequent occurrence, and may be primary or consecutive in order—that is, they may be the original and immediate cause of cerebral disease, or the sequence of changes induced by a neighboring gumma or pachymeningitis. Heubner, Greenfield, Hutchinson, Dowse, Dreschfeld, and others, have chiefly contributed to the present knowledge of this interesting subject. The small arteries are most often attacked, symmetrically at times as regards the two halves of the brain, in distinctly limited areas, where whitish points or nodules become visible to the naked eye. Longitudinal section of vessels thus implicated reveals an obliteration wholly or in part of the lumen of the vascular tube, due to thickening of the inner coat; the middle, clearly defined, being scarcely affected (endarteritis obliterans). The adventitia is doubled or trebled in volume, its cells under the microscope being exhibited as long, parallel, fusiform elements. The obliteration of the lumen, however, is chiefly due to a cellular proliferation between the endothelial lining of the vessel and the fenestrated membrane, resembling a granuloma in appearance. Externally and internally are flattened or fusiform cells, arranged more or less regularly in parallel lines, between which are more irregularly and loosely packed larger cells, mingled with minute fibres of elastic tissue and the vasa vasorum. The endothelium is then finally separated from the membrana fenestrata, and projects into the lumen of the vessel as a vegetation, occasionally forming a second fenestrated membrane on the sides of the vessel-wall. In this way complete stenosis of the tube is eventually produced—an accident rare in atheroma, in which the cellular proliferation is more indolent, more generalized, more disposed to terminate by calcification, and never results in complete obliteration. These accidents are often the causes of the severe headache, vertigo, chorea, epilepsy, and other of the nervous phenomena noted above.

It is by the production of thrombosis or cerebral ischæmia that the arterial stenosis operates to induce the derangement.

A syphilitic periarteritis is described by a few authors (Charcot, Rabot, Bumstead and Taylor), in which circumscribed, lenticular, whitish masses of irregular shape result from an endarteritis affecting the external coats of the vessel, with proliferation also of the media and internal coat. The internal elastic tissue is reported intact, with round-celled infiltration of the muscular layer, and multiplication and dilatation of the vasa vasorum.

The cerebro-spinal nerves may suffer compression by an osseous or meningeal lesion of syphilis sufficient to produce a series of symptoms ranging from formication, hyperæsthesia, and moderate numbness, to complete anæsthesia, analgesia (rare), or paralysis. The derangements of vision induced by syphilitic changes in the optic nerves supplying the muscles that move the globe of the eye have been already considered. In a similar way, the olfactory, sympathetic, and other nerves may be implicated. Petrow, in the cases examined by him where the sympathetic nervous trunks were involved, recognized a pigmentation of the cellular protoplasm, attributed to the deposit of hæmatine in the nervous cells. The endothelial elements were proliferating and surrounded by polygonal nucleated cells, some undergoing colloid metamorphosis. These nervous elements were compressed by an hyperplastic connective-tissue growth, undergoing later sclerosis, and eventually starving the nervous elements into atrophy. The membranous envelope of the latter, after undergoing hypertrophy, may be the seat of fatty metamorphosis.

The treatment of the nervous complications of syphilis is that of the disease in general. The credit of employing large and progressively larger doses of the iodide of potassium in all serious emergencies, with brilliant results, is largely due to American practitioners. The best and simplest way of attaining the end is to administer drop doses of a saturated aqueous solution of the potassic iodide in milk every four hours, beginning with a relatively small dose, five to ten drops (0.33–0.66), and pushing on by increasing one drop each dose until the end in view is reached. By this means the author has, in exceptional cases, given one ounce and a half (48.00) of the iodide in twenty-four hours, with happy effect; and still larger doses have been reached by others. The rule should be to stop the increase at once on the supervention of any toxic effects or marked symptoms of physical protest against the large dose; to then hold at a given point, or to reduce the dose to a point of complete toleration, and to recognize the fact that after the extreme point of toleration has been fully reached, perhaps slightly surpassed, and for a moderate length of time held, further medication of this sort, in the absence of the definite and brilliant results usually attained by its adoption, is useless, and in cases harmful. It should not be forgotten, also, that in the absence of such desired results, mercury in full doses (*e.g.*, calomel one-tenth of a grain (0.0066), every hour or two in any serious emergency) may prove of inestimable value.

The prognosis in syphilis of the nervous system, even in the face of apparently desperate peril, is far more favorable than in the case of nervous symptoms of similar import occurring in those who are not the victims of that disease.

Muscles, Tendons, and Articulations.—Muscular contracture is described by a number of authors as a syphilitic accident occurring slowly or rapidly, and producing fixed flexion or extension of any movable part to which the tendon of the muscle is attached, the latter, on

palpation, being recognized as a rigid and inflexible cord. The joints are not in such cases involved. One or several muscles may be attacked, the biceps being that most commonly affected, the forearm being then flexed at an acute angle upon the arm. The involved muscle may and may not be then the seat of pain and tenderness. A tetaniform involvement of a much larger number of muscles is described also by writers as of occurrence in syphilis.

In the diffuse form of myositis occurring in syphilis, there is diffuse swelling of the whole or a part of a muscle, some redness and œdema of the overlying skin, and pain when the muscular fibres contract. Gummata of the muscles are small, at first firm, later softish, usually globular masses, from the size of a nut to that of an egg, of insidious development, and often, when in process of disintegration, attached to the skin and undergoing the cycle of changes already described in connection with the ulcer resulting from subcutaneous gummata. It is believed that the sheaths of the muscle-bundles are first involved in these changes. They undergo, in some instances, osseous and cartilaginous metamorphoses instead of disintegrating.

The tendons, tendinous sheaths, and aponeuroses may become in syphilis the seat of flattish, triangular, circumscribed, and usually painless tumors, due to effusion in the serous sacs; or to projecting gummata which may break down and ulcerate, leaving a cicatrix whose contraction may subsequently interfere with the function of the muscle to which such a tendon or aponeurosis is attached. Diffuse gummatous thickenings also affect the fasciæ and aponeuroses, more particularly those of the lower extremities.

The bursæ are not rarely affected in tertiary syphilis, more particularly those of the patella and of the tibial tuberosity in women. They begin as single, painless or slightly painful, firm, elastic, or softish gummata, from the size of a nut to that of an egg, which are apt to involve the skin eventually, and to be obstinate under treatment. The author has now in hospital a woman, twenty-five years of age, with the ligament of the left patella fully exposed at the bottom of an ulcer, as large as the palm of the hand, and involving all the neighboring parts, which began as a gummatous bursitis.

Syphilitic rheumatism (arthralgia, pseudo-rheumatism) may be an acute, more often a subacute, polyarthritis with tender and painful points about the articulations, preceded often for days by arthritic pains, as distinguished from simple rheumatism. This complication is remarkable for the failure of acuity in the symptoms, the relative painlessness of the affected joints, the absence of articular swellings (*arthritis sine materia*), and the nocturnal exacerbation of the pain. Hydrarthrosis, most commonly symmetrical and of the knee-joints, though also mono-articular, is both an early and a late symptom of syphilis, and is chiefly remarkable for the extent to which the joints may be distended with synovial fluid, and be yet sufficiently free from pain to permit of performance of their function. It often recurs and disappears for several weeks at a time. The so-called "syphilitic white swelling" is due to fibrous thickenings and subsynovial, gummatous infiltrations in and about the joint. In the author's experience, these synovial effusions have occurred only in the subjects of cachexia, or young male patients of fragile constitution.

The fingers and toes may be the seat of primary, secondary, and tertiary syphilitic lesions, and in both acquired and inherited syphilis. To Dr. R. W. Taylor's exhaustive researches we are greatly indebted for a knowledge of this interesting subject, to which merely a brief reference can be made in these pages.

The affection is more common in hereditary than in acquired disease. In the former the disease may begin in the subcutaneous connective and fibrous articular tissues, or primarily in the osseous and periosteal tissues, and consecutively invade the other structures named. The digit affected, either in one or more phalanges, enlarges insidiously, becomes dense, painful, inflexible, with attached overlying and purplish-red skin. Sometimes an articular hydrarthrosis can be detected; again, one or more of the symptoms resulting from gummatous infiltration. These gummatous deposits are circumscribed or diffuse, and not prone to ulcerative degeneration. Specific dactylitic osteo-myelitis, periosteitis, or osteo-periosteitis, may be a slow, rapid, or relapsing accident, producing in full evolution a balloon- or acorn-shaped, globular, or pyriform swelling, involving one or several phalanges of a single digit, usually the proximal, and more often those of the fingers than of the toes. As sequelæ, may be enumerated inflammatory changes with abscesses discharging a caseous matter, crepitation from roughness of the articular faces of the cartilages, the formation of sinuses, hydrarthrosis, and osseous atrophy after resorption of the gummatous deposit, leaving the shaft of the phalanx more slender and fragile than before. In other yet more marked cases, two conspicuous instances of which were lately exhibited at the author's clinic, the phalanx is reduced by shrinkage till the finger is shortened one-third or one-fourth of its length. The resulting deformity is conspicuous, and almost peculiar to the special disease under consideration.

Cartilages and bones are attacked in both early and late forms of the disease. The most common form of bone disease is an osteo-periosteitis characterized by inflammatory phenomena, vascularization, and exudation, diffuse or circumscribed, of the area of contact of the osseous and periosteal surfaces. The result is declared in the formation of well-defined, rarely poorly circumscribed nodosities in various degrees sensitive, and usually the seat of a characteristic pain, intensely, often intolerably, aggravated at night after retiring to bed. Absorption may result or, much more rarely, degeneration and exfoliation of a thin lamella of bone. In other cases an exostosis results from a plastic effusion between the periosteum and bone, usually circumscribed and flattish, globoid, annular, sessile, or pedunculated, which may undergo eburnation and exhibit compact or cancellated tissue in its structure. When the bone has been infiltrated with a gummatous material which degenerates, it is usually the epiphysis which is the seat of the disorder, though the medulla (osteo-myelitis) and bony substance, or even periosteum and bone, may be involved. Ulceration may then leave a roundish cavity, from the size of a pea to that of a nut, possibly communicating with the medullary canal, filled with a bright-yellowish pulp; the faces of the cartilages become the seat of salient granulations and depressions (scars ?), the size of millet-seeds. At times the diaphysis of the bone is first attacked and the epiphysis secondarily. Often the synovial membrane remains intact.

The "dry caries" or "inflammatory atrophy" of Virchow is a change beginning with vascularization, but unaccompanied by suppuration or ulceration, in which the osseous substance is found wanting in stellate or foveolated pits which may enlarge in the line of furrows representing the Haversian canals. These parts are surrounded by hyperostosis. Bumstead and Taylor look upon these and similar depressions in the osseous substances, when osteoid growth has ceased centrally and is actively progressing at the periphery, as syphilitic cicatrices of bone. The meninges, periosteum, and integument may participate in the formation of such cicatrices, resulting finally in the production of a uniform, thin, contractured, whitish or grayish fibrous tissue, unprovided with vessels.

The various bones of the skeleton are in different degrees subject to the several changes described above. The vault of the cranium is particularly liable, in both external and internal tables, to exhibit single or multiple, circumscribed osseous changes, as also are the sternum, the clavicle, the ribs, and particularly the tibiæ. The substernal and similar pains, noted so frequently as precocious phenomena in the early periods of the disease, are probably associated with transitory osteo-periosteal hyperæmia. In the later periods the nodes that form, whether inflammatory or gummatous in type, are characterized by the same severe nocturnal exaggeration of the pain they excite, and by marked localized tenderness. Some of

the consequences resulting from the pressure induced by intracranial nodes have been described in the paragraphs devoted to the phenomena of nervous syphilis. Gummata of the frontal and temporal bones, forming firm projecting tumors, are at times so conspicuous as to produce marked deformity. Other bones besides those named, *e.g.*, the radius, ulna, femur, maxillary, and, indeed, any part of the skeleton, may become the seat of these lesions. The treatment is that of syphilis in general, more particularly in its tertiary stage. The remarkable effect of the potassic iodide upon many of these lesions is one of the demonstrations, which even the most sceptical are compelled to accept, of the signal efficacy of an ingested drug upon a neoplasm defying local therapy. The dose is to be pushed, to secure marked relief, to any required point precisely as indicated above in the management of nervous symptoms. Indeed, as will be gathered from what has preceded, the same treatment is often urgently demanded in the same patient, at the same moment, for relief of grave nervous complications depending solely upon syphilitic osseous disease. Locally, the mercurial ointments, plasters, and oleates, with occasional use of anodynes, fill an important part.

Hereditary Syphilis.—This form of the disease, the only one not known to originate by an initial sclerosis, is also termed congenital and infantile syphilis. The syphilis of infants, acquired by accidental or intentional transmission after birth, is practically that of acquired syphilis of adults, the differences being chiefly due to the tender skin of the young patient and its extreme liability to nutritional disorders.

Hereditary syphilis is the disease transmitted by inheritance from one or both progenitors to a second generation. Evidences of such transmission to the third generation are extremely rare. The more active the disease in the progenitors, the greater the chances of infection of the offspring.

In inherited, no less than in acquired, syphilis pathologists have recognized micro-organisms which have been claimed to be effective in the evolution of the disease. Doutrelepont, Kassowitz, Hochsinger, Kalisko, and Chatzen have both detected and failed to detect streptococci in the viscera of children affected with hereditary lues, more particularly in the skin, mucous surfaces, bones, and liver. In some instances the lymph-channels have been found choked with micro-organisms of this kind, which fact has suggested to Chatzen that the cachexia of some patients in this category was a streptococcus-septicæmia.

Relative Influence of the Parents in the Transmission of the Disease.—The father alone, when the victim of an active constitutional syphilis, is capable of transmitting the disease to his child without infection of the mother. It is probable that he does not possess this power before the disease is actively displayed in his own person by constitutional symptoms. It is certain that this power is greatly weakened while he is under the influence of mercury; is weakened and regained during the respective periods of repose and activity so commonly observed in the disease; and is finally extinguished by time. It remains to be admitted that the cases in which the father alone is thus responsible for syphilis in the second generation are far fewer than those in which the mother alone is thus responsible; and that the power of such transmissibility is positively denied to the father by the followers of Cullerier, Oewre, and others.

The mother alone, the father being unaffected, may transmit syphilis to the child, if she be the victim of an active constitutional disease. If conception occur later than the twentieth day after the appearance of the earliest syphiloderm, the product of such conception is almost certainly doomed to destruction, abortion of the ovum commonly following from the third to the seventh month. The woman, however, profoundly syphilitic, may abort or miscarry in consequence of the cachectic state to which she is reduced by syphilis, and may thus throw off, as in any cachectic condition, the unaffected germ. Again, the child may escape entirely by the operation of that inscrutable law which ever and again protects the offspring from the vices and errors of the parents. Lastly, in a series of pregnancies, abortions may be followed by miscarriages; the latter by stillbirths at term; then by viable infants exhibiting symptoms of syphilis before the fourth month of life; and, lastly, by the birth of children in whom syphilis can never be recognized, the power of transmission being weakened till it is wholly lost in the process of time.

If the mother be affected after conception, it is probable that she cannot convey her disease to the child. She may abort or miscarry in consequence of the anæmia induced by her own disease, but it is improbable that, either in the first or latter half of pregnancy (both periods have been claimed as those of special danger), the virus can be transmitted through the utero-placental circulation. Cases have been cited in support of both views as to the possibility and impossibility of such transmission, the cases cited in support of the affirmative view being in the main defective, by reason of failure to demonstrate both perfect immunity of the father and positive syphilis of the child.

A healthy mother may bear a syphilitic child. On this point also there has been much division of authority. The large number of all mothers who bear syphilitic children are themselves unquestionably syphilitic. But the possibility that a syphilitic child may be infected by inheritance from the father alone, the mother remaining sound (precisely as is the case when the child is sound and the mother healthy), is demonstrated by numerous facts. Dr. Taylor, of New York, and the author have in this country substantiated by reported cases the facts set forth abroad by Kassowitz and others. The well-known law of Colles is urged in support of such transmission. That law formulates a well-known clinical fact, viz., that the mother of a syphilitic child is never infected at the breast by her offspring—the secretions of whose diseased mouth are infective for all healthy persons. A few exceptions are reported to this law, so few and so inconclusive as to rather more fully establish its general applicability. It is probable that the system of the mother, after the bearing of such children, is so modified as to render her incapable of receiving the disease. If the sound child be infected at the moment of birth by direct contact with recently developed, secreting, primary, or secondary lesions existing upon any part of the external genitals of the mother (an accident reported in a few cases), the result is acquired infantile, and not inherited, syphilis.

The clinical symptoms of hereditary syphilis are first the death of ovum or fœtus. These products of conception are then ushered into the world either undistinguishable from the dead products of pregnancies where no syphilis has interfered; or macerated, the epidermis being readily separable from the corium, which is deeply congested, or, for the reason first named, raised into bullæ, and the viscera in various ways are profoundly altered. In a second list are to be classed stillbirths, and the birth of children surviving but a brief time. These may be apparently unaffected by disease; or covered, in various degrees, with bullous lesions produced by passive exudation of fluids elevating the loosened epidermis from the corium; or suffer from visceral changes. In a third category may be named children who survive for various periods to maturity. One-third of all are thought, however, to perish without attaining that development. Many perish before the second month; those who survive commonly exhibit the symptoms of inherited syphilis in the same period, even if no signs are apparent at birth. Hereditary syphilis is rarely deferred in its manifestations after the fourth month. Cases reported as of late inherited syphilis, where the first symptoms of that disease were manifested at the period of puberty, for example, are regarded by most experts with suspicion.

The *placenta* may be the seat of a diffuse or circumscribed gummatous infiltration. The two may concur. In such cases the syphiloma is characterized as usual by the firm, external, fibrous, grayish-tinted layers surrounding a softer, yellowish central mass. Hydramnios is

also counted among the possible syphilitic changes of pregnancy.

The skin of the victim of inherited syphilis is subject to many changes resembling, for the most part, those recognized in the acquired form of the disease. It is commonly seen to be either flaccid and wrinkled, or tightly stretched over the bones as if deprived of its panniculus adiposus. In this way the characteristic little-old-man and little-old-woman appearance of the syphilitic infant is produced. The skin has, moreover, a not less constant and characteristic sallow, yellowish, earthy hue. Manifestly the nutrition is profoundly impaired, and the child exhibits a series of symptoms, such as vomiting, diarrhœa, etc., which indicate that not the skin alone but other organs are participating in the disease. As a matter of practical moment, it is well for the practitioner to remember that a healthy-looking, well-nourished child, six months and more of age, without pulmonary or gastro-intestinal disorder and no signs of disease save a suspicious-looking eruption upon the skin, is probably *not* the victim of inherited syphilis.

The macular or erythematous rash (roseola) appears usually over the belly, face, neck, palms, extremities, and other parts, in the form of roundish or oval-shaped macules, from the size of a split pea to that of the finger-nail, of the copper-and-reddish shade, soon refusing to yield under pressure, often seen as the earliest cutaneous symptom of the disease. The spots may enlarge by multiplication or coalescence ; may, in cases, become elevated or covered with scales ; or may undergo fissure.

Papules, mucous plaques, mucous patches (of the skin and mucous membranes), and condylomata lata are all phases of one and the same process of proliferation in hereditary syphilis. The most common of all is the occurrence of these flattened papules or patches in the nasal cavity, furnishing a serous discharge which rapidly becomes purulent or hæmorrhagic in type, and which by desiccation soon blocks up with crusts the nasal passages. As a consequence a characteristic "snuffles" follows, the child abandoning the nipple to get breath, and even in sleep uttering a diagnostic snore. On many occasions physicians, hearing this suspicious respiratory sound in infants brought to them for relief of cutaneous ailments, have thus obtained a clew to the real nature of the malady. Specific coryzas of this sort may progress to ulceration or osseous necrosis. Similar roundish or oval-shaped patches, or (after confluence) large sheets of involved mucous surface, may be recognized in the mouth, furnishing a highly contagious secretion. In this way the tongue, lips, gums, and fauces may be involved, and the child may be rendered incapable of seizing the nipple with the mouth. At the angles of the mouth, also, on the muco-cutaneous surface, flat papules, condylomata, or secreting patches may conceal the natural outlines of the parts, be extensively crust-covered, or even superficially or deeply ulcerated.

Over the general surface of the body, small or large, flat or, more rarely, acuminate papules, copper-colored and reddish in hue ; smooth or scaling, symmetrical, and generalized or limited to a single region, may be conspicuous. They may coalesce, furnish a patch of infiltration, and even extensively ulcerate. The most frequent manifestations of this type, next to the nasal lesions accompanied by "snuffles," are the condylomata about the anus, from the size of a pea to that of an egg and larger, flattened, whitish or reddish lesions, secreting, elevated, and distinctly circumscribed.

Vesicles, isolated or confluent, conical or flattened, from the size of a pin-head to that of a split-pea, may also spring from macules or papules, rest upon a brownish and reddish base, and be filled with serum or a sero-purulent fluid. They are rare lesions. Pustules, from the size of a pin-head to that of a split-pea, are more often seen, with and without a previous or concurrent evolution of vesicles or papules ; often as a metamorphosis of the latter. The skin thus affected is commonly infiltrated, purplish, and covered with brownish or greenish crusts. Beneath these may be simply excoriation or ulceration. The genital region, face, scalp, and lower extremities may be involved ; rarely the entire surface of the body. The scarring which results is not conspicuous.

Bullæ are grave and unfortunately common symptoms of inherited syphilis. They may, as indicated above, be conspicuous at birth, single or multiple as to number ; or develop later as wine-colored, circumscribed patches of integument ; first pea-sized, later as large as an egg, an orange, or a cocoa-nut, filled with serous, lactescent, or hæmorrhagic contents. The palms and soles are frequently involved. The areola is violaceous, often infiltrated and raised. The brownish crusts cover ulcers with a foul, hæmorrhagic, or diphtheritic floor. Death usually ensues, when the eruption is at all generalized, in the course of a few days. Furuncles, beginning as circumscribed cutaneous or subcutaneous and indolent nodules, from the size of a pea to that of a nut, may be in some cases so numerous as to constitute a characteristic and even symmetrical eruption. They may, after a typical suppuration, discharge a core by sloughing, or break down into conical ulcers of the crateriform shape.

Tubercles and gummata may observe almost the same cycle. They also begin as roundish or irregularly knobbed, usually subcutaneous nodules, which break down, furnish an irritating, semi-purulent or serous discharge, and finally result in ulcers of the typical aspect already described as of occurrence in the acquired forms of syphilis. These ulcers may also follow the less circumscribed gummatous infiltrations of the skin and subcutaneous tissues.

Many of the grave cases of profound destruction of tissues about the face (eyes, nose, lips, jaws, etc.), illustrated in the works of the best authors on the subject of hereditary syphilis, originated in gummata whose ulcerative processes, beginning in or beneath the skin, spread thence to muscles, fascia, periosteum, and bone.

The *larynx, trachea,* and *neighboring parts* may be, in early inherited disease, the seat of ulcerations resulting in the production of stenosis, cicatrization, and bridles stretched between adjacent walls, so as to interfere with the function of the organ implicated. The late forms are described by Fournier as diffuse hyperplastic, circumscribed gummatous, and sclero-gummatous—the last-named a combination of other forms. These may be serious in consequence of the results recognized in acquired disease, viz., production of (chiefly laryngeal) dyspnœa, glottic spasm, acute œdema, and sudden death. Sclerosed masses, subsequently exhibiting a central yellow softening, have been recognized by Lebert and others in the lungs of children dead of inherited syphilis, which are believed to be gummata of these organs.

The mucous lining of the *alimentary canal* may be the seat of changes similar to those observed in the exposed mucous surfaces of the subjects of the disease. Circumscribed hyperæmia and even indurated hyperplastic, as well as ulcerative, patches have been recognized about the solitary and agminated glands. The liver may be, after the occurrence of specific changes in the walls of its vessels, hypertrophied, dense, and resisting ; or the seat of pedunculated tumors, or of diffuse or circumscribed parenchymatous gummata. These may be miliary or nut-sized, and surrounded by the usual fibro plastic envelope. The spleen is probably always involved in the child affected with inherited syphilis. It may be the seat of a partial or general perisplenitis, capsular or subcapsular in situation ; is always greatly increased in size and weight ; and may undergo later, under treatment, reduction to its normal size, or, in other cases, lardaceous metamorphosis. The increase in size and weight which has been noticed in the pancreas is different, in that it seems to be accompanied by a sclerosis due to hypertrophy of the interstitial connective tissue.

The *suprarenal capsules* may be involved in a partial or complete peri-capsulitis ; as also in a parenchymatous deposit of miliary gummata. Fatty, colloid, and gelatiniform degeneration may be observed as a result of these morbid changes in both capsule and substance proper. The *kidney* has been found enlarged and also containing one or many miliary, whitish or yellowish, circumscribed gummata, or diffuse infiltrations. The

Syphilis.

origin of these lesions has been traced to proliferative changes in the connective-tissue stroma of the organ. Here, too, colloid and fatty degeneration has ensued—in rare cases, ulcerative destruction. One or both *testes* may be involved in male patients, the disorder beginning with an indolent tumefaction of the testis proper (the epididymis being usually spared), smooth, lobulated, and accompanied or not by moderate hydrocele and scrotal engorgement. Fournier calls attention to the discovery, in patients exhibiting tardy symptoms of inherited disease, of small, densely indurated testicles, either arrested in development or the fruit of the gummatous changes wrought in earlier periods of the disease. It is possible that the ovaries may be similarly involved (Panot).

The *hair* and *nails* are affected in hereditary as in acquired syphilis, chiefly after involvement of the tissues on which they depend for nutrition and support. In this way patches of alopecia become visible in the scalp. The nails are surrounded by a ring of purplish infiltration; or papulo-pustules, degenerating into ulcers, undermine the matrix and possibly finish with loss of the nail and formation of a cicatrix. The deformity of the distal phalanx in these cases is strikingly characteristic, presenting as it does a livid club-like enlargement, often both tender and painful, bearing, usually on one side only, a semilunar ulcer with sero-purulent secretion, foul base, and distorted or displaced nail. The nail-substance in these cases may be friable, eroded, "worm-eaten" in appearance, frayed, or laterally ridged and furrowed.

The changes so strikingly characteristic of inherited syphilis in the *eye* (keratitis, etc.), *ear* (remediless deafness of late inherited syphilis), and *teeth* (Hutchinson's changes), have already been described. A group of symptoms less classical and constant are puriform depots in the *thymus gland*, supposed to be abscesses (Dubois); glandular abscesses due to the irritation of neighboring cutaneous lesions (*e.g.*, in the neck, when associated with scalp or mouth disease); hæmophilia, or hæmorrhagic symptoms appreciable at birth or soon after, in the cutaneous or mucous surfaces, probably due in greater measure to the cachexia of the disease than to specific changes; stenosis of veins and arteries (perhaps associated with gummatous changes in the vascular wall similiar to those occurring in the endarteritis obliterans of acquired syphilis); and fusiform swellings of the synovial sheaths over the metacarpal bones (Bumstead and Taylor).

The affections of the *bones* in hereditary syphilis have been exhaustively studied in the last decade by Wegner, Waldeyer, Parrot, Taylor, Fournier, and others. They are among the most common of all the symptoms of the disease, being next in order to the ocular changes. All the phenomena long ascribed to rickets are to-day referred to inherited syphilis. Osteochondritis usually affects the diaphyso-epiphyseal extremity of the forearm, leg, arm, or thigh, but all the bones may be involved in the newlyborn infant, and that as the sole manifestation of the disease, or in conjunction with skin and other lesions. A partial or complete annular swelling, smooth, or irregular, or ridged, is then found, of insidious or rapid development, encircling the extremity of the bone (distal extremity of ulna, sternal extremity of clavicle). There may be articular effusions in the contiguous joint. The swelling may disappear under treatment, or degenerate by ulceration as in gummata, resulting in loosening, separation, or destruction of the epiphysis or cartilage; or ultimately result in death by exhaustion. The bone may be shortened as a result, or invested with a thickened periosteum. The pathological changes may be described briefly as due to proliferation of the cartilage cells, with mamelonation of the epiphyseal surface, and calcification of the osteoid processes. Periosteal and perichondrial thickenings follow, conjointly with retarded osteogenesis at some points.

Osteoperiosteitis is a later bone symptom of inherited syphilis, affecting predominantly the tibia, but also the ulna, radius, cranial, and other bones, often more than one bone in one subject of the disease, and then at times symmetrically. The hyperostosis resulting may distort the tibia so as to produce the so-called "sabre-blade" deformity, its voluminous mass forming a curve, with an anterior or lateral convexity, painful, tender, and indolent of development; or it may result in characteristic multiple cranial hyperostoses of the temporal and frontal regions. All these forms may result in necrosis, ulceration of bone, and formation of fistulous tracts through which sequestra may be removed.

In gummatous osteomyelitis the medullary canal, after degeneration of a gummatous infiltration, may be the seat of a cheesy tissue here and there enclosing solid masses, surrounded by layers of newly formed bone.

The syphilitic dactylitis of inherited resembles that of acquired, disease, the swellings attacking slowly or rapidly, with or without pain, one or more of the proximal phalanges, or metacarpal or metatarsal bones. In all these bone lesions the joints may participate secondarily, or the synovial membrane or fibrous capsule may be first to induce a hydrarthrosis or tumefaction, which may go on to degenerative changes involving cartilage and bone, or be averted at any stage by treatment.

The *nervous system*, in inherited syphilis, is chiefly involved after the occurrence of structural changes in the meninges and other neighboring parts. Fibrous and gummatous thickenings and infiltrations, diffuse and circumscribed, may implicate one or more of the meningeal layers, agglutinating them to each other or to the nervous structures they enclose. Periosteitis of the surfaces in contact with these membranes, intracephalic scleroses and gummata, and occlusions of the lumen of the cerebral vessels, may here, as in acquired disease, be followed by a long series of nervous symptoms, dilatation of the pupil, facial paralysis, paraplegia, hemiplegia, epileptiform seizures, hydrocephalus, idiocy, and various grades of failure of intellectual development and vigor. Fournier, in describing the late forms of this complication, lays stress upon the occurrence of severe and persistent cephalalgias, similar to those so frequently recognized in acquired syphilis of the nervous system. The same author believes that there is an heredito-syphilitic tabes, and possibly also a sclerosis *en plaques*. The paralyses resulting from compression or other changes in the nervous trunk chiefly involve the ocular muscles.

The *treatment* of the mother affected with syphilis, and pregnant or nursing a syphilitic infant, is usually indicated. Mercurial inunction of the infant by smearing its flannel roller with oleates and salves, is an efficient means of introducing the metal when it is required. Calomel, or the gray powder, may be given, one grain to one-twentieth of either (0.066 to 0.0033) rubbed up with sugar of milk, and placed upon the tongue of the infant, three or four times daily. The dose can be nicely adjusted to the requirements of each case. The bichloride may be substituted in combination with syrup of licorice or of ginger. Ten drops may be given of a two-ounce (64.0) solution, containing from one-fourth to one grain (0.0160 to 0.66) of the sublimate to the ounce (32.0). Inunction is, however, far preferable for the majority of cases, with the administration of cod-liver oil by the mouth. When mercury and the iodide of potassium are both indicated (more particularly in the management of osseous lesions), the several combinations known as the syrup of Gibert are useful, *e.g.*:

℞.	Hydrarg. biniodid	gr. j.	(0.66)
	Potass iodid	℥ ss.	(16.0)
	Syr. glycyrrhiz. (vel zingiber.),		
	Aq. dest	āā ℥ ij.	(64.0)
M.			

Of this solution the infant under the fourth month can take from five to ten drops in water, the larger dose being gradually reached. Similarly, in all portentous cases, the iodide of potassium may be administered in drop-doses of a saturated solution to the point required to produce any desired effect, as already described in the treatment of nervous syphilis in the acquired form. In all cases the diet and hygiene are highly important considerations. The heredito-syphilitic child should be at the breast of the mother (and at the breast of none other), if it can be thus properly nourished. The local manage-

ment of the mouth, the ano-genital region, and all syphilodermata is important, and to be conducted on principles heretofore indicated. Tonics are often useful. The prognosis is grave in all severe cases. In viable children, free from visceral complications, much can be accomplished by treatment.

TREATMENT OF SYPHILIS.—The chief point of importance in syphilis is the non-medicinal management of the patient, without a proper knowledge of which the most skilful use of drugs is ineffective. This introduces to the wide field of diet, hygiene, climate, and occupation of mind and body. The diet should be nutritious, and should exclude alcohol in all forms not specifically directed by the practitioner, with a view to securing its valuable tonic (not stimulating) effects. Tobacco in every form is best discarded, as having an injurious effect upon the nutrition in general, as well as upon the mucous surface of the mouth, which constitutes such a fertile field for the development of mucous patches. The body should be sponged daily with cool or tepid water, and then briskly scrubbed till warm, when the general surface is not the seat of syphilodermata forbidding such a course. The skin should be properly protected by woollen underwear. To the immense majority of syphilitic patients sexual indulgence should be absolutely prohibited, the few exceptions being furnished by husband and wife both convalescent from unmistakable disease. Most patients are better for regular and systematic attention to their usual occupation, though the latter should not unduly tax the mental or physical powers. The bowels should be evacuated daily. Exercise in the open air and due regulation of the hours of sleep should not be forgotten. In many cases, where the purse of the patient will permit, the recreation of travel, a sojourn at the sea-shore, or a change from an inhospitable to a mild climate, are valuable steps toward recovery.

In a small percentage of cases the expectant or tonic treatment of syphilis, conducted largely by the measures described above, aided by the use of tonics (ferruginous, bitter, acid), suffices for what seems to be a cure. Indeed, no observer of large experience can deny that cases of exceedingly mild and benignant syphilis are often untreated and exhibit no recurrence.

The immense preponderance of cases, however, is on the other side of this slender border line of safety; and the danger of such an expectant course, for most patients, is sufficiently grave almost to furnish the basis of serious charges of neglect and carelessness against the practitioner who habitually pursues it.

Mercury is to-day, as for nearly four hundred years past, counted the most efficient of all drugs in the treatment of syphilis. It is given by the mouth in the form of the protiodide, biniodide, bichloride, calomel, gray powder, blue mass, or other combinations of the metal. The protiodide is deservedly popular with American physicians, and may be given in one-fifth of a grain (centigram) granules, pellets, or disks. It is usual to begin with one after each meal, and to increase gradually till some constitutional effect is produced, such as looseness of the bowels, slightly increased flow of saliva, or moderate abdominal pain, after which the dose is reduced. Keyes suggests at this point a "tonic" dose—one which can be tolerated for months at a time without inconvenience, and reached by the reduction of the dose described above. For speedy effect, calomel is employed in doses of one-tenth of a grain (0.0066) every hour; and for slower effect, less often. It is well administered in powder rubbed up with sugar of milk. The mercurial pill has the advantage of being readily combined with iron, as *e.g.*:

℞. Pil. hydrarg.................. ℈ij. (2.66)
Mass. Vallet (pil. ferri subcarb.)...................... ℈ss. (0.66)
Opii extract.................. gr. iv. (0.26)
M. Ft. pil., No. xx. Sig.—One after meals.

The dried ferric sulphate, quinine, ergotine, and aloes, may each, when indicated, be incorporated in these or similar pills.

The bichloride is often best combined with iron in some such acid solution as:

℞. Hydrarg. bichlorid.. grs. i.–ij. (0.066–0.133)
Ferri tinct. mur.,
Acid. mur. dil....āā ʒ ij.–iv. (4.–16.)
Syr. zingiber. (vel sarzæ)............ f ℥ ij. (32.)
Aq. dest... .....ad f ℥ vj. (192.)
M. S.—A teaspoonful in a wineglassful of water after each meal.

Solutions of the bichloride effected with the aid of alcohol or with an equal quantity of the muriate of ammonium are also useful.

The biniodide is usually administered by decomposing corrosive sublimate with the potassic iodide, and dissolving the precipitate in an excess of the same salt, *e.g.*:

℞. Hydrarg. bichlorid........... gr. j. (0.066)
Potass. iodid................ ʒ ij. (8.)
Aq. dest.................... ℥ iij. (96.)
M. S.—A teaspoonful in water after meals.

The Gibert formula, modified variously by almost every author, is nearly as follows:

℞. Hydrarg. biniodid........... gr. j. (0.06)
Potass. iodid................ ʒ j. (4.)
Aq. dest.................... ʒ j. (4.)
M. Filtra, deinde adde syrup. aurant. cort................. ℥ vj. (192.)
S.—One to two teaspoonfuls in water after eating.

Combinations of mercury and the potassic iodide are employed chiefly in the so-called "mixed" treatment of syphilis; in lesions that are transitional in type between secondary and tertiary stages; and also in many precarious or rebellious symptoms in the earlier stages of the malady. Pills of the bichloride and biniodide are usually objectionable on account of their tendency to the production of irritative effects, but are in some cases given with great advantage. From one-sixteenth to one-fortieth of a grain of either (0.004 to 0.0016) may thus be administered after meals.

Mercury is of great service when applied by vapor in fumigation. This method is generally, in the larger cities of the country, relegated to the bath-houses, but by the aid of a chair, a blanket, and Lee's or Maury's lamp, it can be employed at the residence of any patient. From one to three drachms (4.–12.) of calomel, cinnabar, or the gray oxide, or two or more of them in combination, are used for the production of the vapor when placed on the metallic plate of the lamp. Steam is furnished by water boiling in the chamber designed for that purpose, and the naked and sweating skin of the patient, wrapped in the blanket over the lamp, is thus subjected two or three times a week to the fumes of the mercury.

The uncleanly, but very effective, method of introducing mercury by inunction is popular abroad, but used in this country chiefly by experts, in hospitals, and at certain springs enjoying repute for the relief of this disorder. Equal parts of the twenty per cent. mercuric oleate and scented vaseline, or the ordinary mercurial ointment, may be used, one drachm (4.) or more being rubbed at night before retiring into different portions of the skin (selecting a new region each night), and removed by a bath in the morning.

Hypodermatic injections of mercury in various forms are popular upon the Continent of Europe, but much less frequently employed in England and America. They are rapidly effective when used. They have been the subject of much favorable and adverse criticism, and even at this late hour are both praised and decried by leading syphilographers. They are subject to the disadvantage of requiring a physician for the administration of each dose, and therefore more suited to hospital than to private practice. The following formulæ have been employed: Calomel, one and one-half to three grains (0.10 to 0.266), rubbed up with about twenty-four minims (1.50) of pure glycerine (Scarenzio); corrosive sublimate,

four grains to the ounce (0.266 to 32.0) of distilled water; fifteen minims (1.00) to be injected every two or three days (Lewin). These solutions have been modified by incorporating with them one-tenth of a grain (0.0066) of the acetate or of the sulphate of morphine, to relieve pain; and the chloride of sodium, four parts to one of the bichloride, to render the solution less irritating. As these subcutaneous injections are liable to be followed by abscesses, attempts have been made in the direction of securing a soluble albuminate or peptonate of mercury, all of which have proved unsatisfactory. Solutions of the bicyanide, biniodide, nitrate, and formidate of mercury have also been recommended. None of these devices has yet rivalled in popularity the solutions of corrosive sublimate in distilled water.

When mercury produces its happiest effects in syphilis, by any mode of administration, the symptoms diminish or disappear, and the patient actually gains in weight. This has led to conclusions respecting a so-called "tonic" effect, which it is supposed by some authors to produce when properly administered. When improperly employed, it is not responsible for many of the results popularly ascribed to its influence. These are chiefly syphilitic symptoms of patients misinformed as to the nature of their disorder. The statistics collated by the physicians of the great Russian mercury mines, of disease observed among the workers in the metal, include none of the symptoms popularly ascribed to the influence of this metal in syphilitic patients—mouth patches, rheumatism, eruptive symptoms, etc. They are all in the direction of salivation, and, in grave cases, of maxillary necrosis. Tenderness of the gums, moderate fetor of the breath, slight increase in the salivary flow, noticeable indentation of the sides of the tongue by the teeth, and tumefaction of the mucous membrane—these are the first signs of a toxic effect which may increase, if the drug be further pushed, to the extreme of complete salivation, with loosening and even falling out of the teeth. In the modern treatment of syphilis no such effects are desired, or even attained. The milder of these manifestations readily disappear under appropriate therapy: tepid gargles of milk, flaxseed tea, or sweetened or demulcent water, containing one drachm (4.) of potassium chlorate to the pint (500.) of vehicle; a liquid and nutritious diet; abstinence from iced, alcoholic, spiced, acetous, and hot articles of food and drink; suspension of the mercurial; laxatives sufficient to secure complete evacuation of the bowels; and often a tonic, not containing the mineral acids.

Iodine and its compounds are useful in combination with mercury and without such union. They are more available in tertiary or late secondary symptoms, but may be often employed with the greatest advantage in the earliest symptoms of the disease. The articles of the class most used are iodine, iodoform, and the iodides of lithium, sodium, starch, and potassium. No one of these is equal in value to the iodide of potassium, or enjoys to the same degree the confidence of the profession. It may be given alone or with mercury by the mouth; or it may be given by the mouth when mercury is employed by inunction or fumigation; or it may be given in alternation with one or more of the courses named.

It is always best administered in solution, from three grains to twenty (0.26 to 1.33) given in distilled water, milk, or any other vehicle preferred, such as cinnamon water, or one of the various syrups employed as vehicles by the druggist. The method of administering the iodide of potassium in largest dose, gradually reached, from one drachm to an ounce (4.0 to 32.00) in the twenty-four hours, has been fully described in the paragraphs devoted to nervous syphilis. Employed with all due precautions it furnishes one of the most brilliantly effective of the measures at hand in the grave emergencies of the disease. When its morbid effects are produced, these may become apparent after the exhibition of the smaller doses. Among them may be named severe coryza, with œdema of the lids, lips, and glottis; salivation; gastro-intestinal distress and tenderness; and a series of cutaneous eruptions. In the order of frequency the latter are acne-form papulo-pustules; furuncular lesions; purpura; tubercles; erythematous macules; bullæ; and eczemaform patches.

An enormous number of medicinal articles, beside those named, have been used in the treatment of syphilis. Some are indispensable in the management of most cases; some have a doubtful effect; many are absolutely worthless. In the first class may be named the ferruginous tonics; the mineral acids (not to be given simultaneously with a mercurial); cod-liver oil; quinine and the vegetable bitters; alcohol, judiciously administered; and, in particular, the fluid extract of erythroxylon coca, first warmly recommended by Taylor in the management of syphilis, and fully endorsed by the author, who has employed it with advantage in many cases. In the second class may be named sarsaparilla (probably having no other than a purely "stomachic" value); the "McDade formula" (equal parts of the fluid extracts of smilax, sarsaparilla, stillingia sylvatica, kappa minor, and phytolacca decandra, with one-half of one part of the tincture of xanthoxylum carolinianum; and Zittman's decoction (probably efficient chiefly for the mercury it contains). In the last class may be named nitric acid, gold, thuya, cascara, berberis aquifolium, and the mass of proprietary preparations, many of which, though advertised as "purely vegetable" compounds, depend for a short-lived popularity upon the mercury or iodine which they contain. None of the mineral springs, in this country or abroad, which enjoy a reputation in the treatment of syphilis, supplies a water which can be demonstrated to possess a therapeutic value outside of the climatic, hygienic, and, indeed, medicinal effects obtained by residence and treatment by physicians in the districts where such springs are found. The waters of the well-known Hot Springs of Arkansas, in this country, have never yet been shown to possess any medicinal virtue; and the number of syphilitic patients who annually resort thither and reap some advantage from such a course are, for the most part, those who have been treated there with mercury or the iodine compounds by their physicians. Even better results might have been obtained in localities more commended to the intelligent physician on the basis of sanitation. The so-called process of "syphilization" has not survived its brief period of notoriety. It was based upon a confusion respecting the nature of the syphilitic and the non-syphilitic sore, and is now not more than a curiosity in the literature of syphilis.

No limit can be set to the length of time which should be assigned for the treatment of the disease. The average patient requires careful observation and treatment for from two to two and a half years. Many require this for a far longer period. Mild cases may require less. No guarantee of future immunity can be given any patient on the conclusion of treatment, though probably seventy-five per cent. of them all have no symptoms of returning disease after the proper management of their cases by a competent physician. Two years at least should elapse after a mild syphilis before a patient of either sex should be permitted marriage with an uninfected person. In any case, one year of immunity should certainly precede the marriage of an infected man or woman. Two years of immunity is required by some of the larger insurance companies before accepting life-risks of the infected. Syphilis, however, is, as a matter of fact, one of the most readily managed and promising of all diseases that affect the human race. As distinguished from them all, its prognosis may be pronounced good. It may often disfigure, but it rarely destroys, its victims. As against the frequent fatality in pneumonia, variola, typhoid fever, or erysipelas, its statistics include an overwhelming preponderance of infected subjects in whose later years it figures only among those indelible reminiscences which teach the sternest lessons of life.

LITERATURE.

The literature of syphilis has accumulated to such an enormous extent that anything like a full bibliography, in the limits assigned to this article, would be impossible. Appended is a brief but selected list of titles, embracing a few of the older classics of syphilitic literature, a number of the modern standard treatises devoted to the subject, and some of the

more important and quite recent contributions to its several departments which have appeared in special and general periodicals:

Astruc, John: A Treatise of the Venereal Disease. London, 1737.
Althaus, J.: Medical Record, October 16, 1886; British Medical Journal, 1883, p. 887; Lancet, December, 1883.
Arthur, G.: New York Medical Record, December 16, 1886.

James Nevins Hyde.

SZCZAWNICA, though little known in other countries, is one of the most frequented and popular spas in Austrian Poland. It is situated in a pleasant hill-country, lying at an elevation variously estimated at from 1,100 to 1,700 feet above the sea. The climate is mild and agreeable. There are six mineral springs here, with a temperature of from 48° to 52° F., of which the Magdalenenquelle is the richest in mineral ingredients. The following is the analysis of this spring, as given by Kisch in Eulenberg's "Real-Encyclopädie." One litre of water contains:

	Grammes.
Sodium bicarbonate	8.447
Sodium chloride	4.615
Sodium sulphate	0.022
Magnesium bicarbonate	0.786
Calcium bicarbonate	0.874
Ferrous bicarbonate	0.010
Potassium chloride	0.091
Sodium iodide	0.0016
Sodium bromide	0.0085
Organic matters, etc	0.2949
Total	15.1500
	Cub. ctm.
Free carbonic acid	711.5

The waters are given internally and in the form of baths, and milk and whey are also extensively employed.

Szczawnica enjoys a high reputation in the treatment of subacute and chronic catarrhs of the respiratory passages, chronic pneumonia, pleurisy, incipient phthisis, and catarrhal gastritis. It is also frequented to some extent by those suffering from the so-called scrofulous affections of the joints, glands, and skin. The accommodations for visitors are said to be good, and obtainable at a moderate price. *T. L. S.*

TAMARIND (*Tamarindus*, U. S. Ph., Br. Ph.; *Pulpa Tamarindorum Cruda*, Ph. G.; *Tamarinier*, Codex Med.). The preserved pulp of the fruit of *Tamarindus Indica* Linn.; Order, *Leguminosæ Cæsalpinieæ*. The tamarind is a large, handsome, widely spreading, locust-like tree, with rough, dark-gray bark, and rather small, cassia-like, abruptly pinnate leaves of from eight to sixteen pairs of oblong-blunt, oblique leaflets. Flowers, in axillary or terminal racemes of eight or ten each. Calyx irregular,

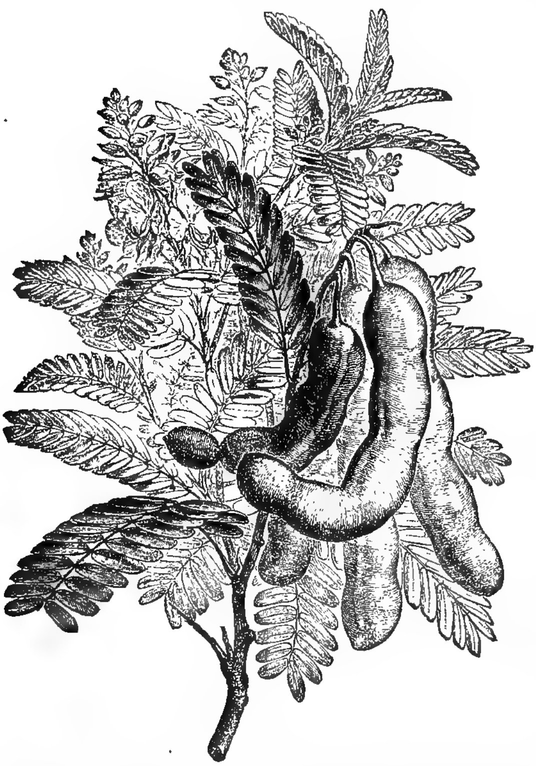

FIG. 3749.—Tamarindus Indica; flowering branch with fruit. (Baillon.)

of four lobes, the upper larger than the others, and colored. Petals three, the upper one smallest, yellow, veined with red. Stamens three, united below. Ovary one, curved upward, one-celled, many ovuled. The fruit is a flattened, curved, solid "pod," from three to six or more inches long; smooth, yellowish-brown externally, with a brittle shell, and a firm acid pulp surrounding the seeds. The pulp contains a skeleton of fibrous bundles running lengthwise over the seeds. The tamarind-tree grows now in all tropical countries, and is, besides, extensively cultivated. It came originally from the Old World, presumably from Africa, but is equally abundant in India, Australia, and the West Indies. The earliest knowledge of tamarinds appears to come from India. They were introduced into Europe during the middle ages.

COLLECTION.—When the fruits are ripe, the outer shell (epicarp) becomes brittle, and is broken between the fingers and removed. The stringy pulp is then packed in kegs and covered with boiling syrup. In this way the West Indian tamarinds, which comprise most of those

that reach our market, are prepared. In the East, sugar is often used instead of syrup, or they may be packed dry, without any sweetening, in a hard, semisolid mass. The seeds are always included.

Preserved tamarinds, as they reach us, are in a moist, reddish-brown, pulpy, stringy mass, with numerous flattish-quadrangular, smooth seeds, and a little thick, dark syrup. They have a pleasantly sourish-sweet taste. Mixed with water they make a pleasant acid drink, which was formerly used in fevers and other forms of sickness. They are very little employed at present.

COMPOSITION.—*Citric acid*, eight or nine per cent., is the most important substance. One and a half per cent. of *tartaric acid*, a little *malic acid*, and, say, three per cent. of *potassium bitartrate*, are adjuvants to the former, and add to the acidity of the fruit. Gum, jelly, and ordinary vegetable matters, and in our preserved tamarinds the sugar that is added, complete the list of ingredients.

USES.—Tamarinds are rather an agreeable luxury than medicine, and in some countries are consumed extensively as a preserve. Here they are used to make a refreshing acid drink, or as an adjuvant to some laxative compound. The Confection of Senna (*Confectio Sennæ*, U. S. Ph.) contains ten per cent. of them. Dose of tamarinds indefinite.

ALLIED PLANTS.—This is the only plant in the Genus. For the Order see SENNA.

ALLIED DRUGS.—Lemons, Barberries, Sumach, Prunes, and other fruits. *W. P. Bolles.*

TANSY (*Tanacetum*, U. S. Ph.; *Tanasie*, Codex Med.). *Tanacetum Vulgare* Linn. (*Chrysanthemum Tanacetum* Karsch), Order, *Compositæ*, is a well-known garden plant and weed, introduced from Europe and thoroughly naturalized. It has a characteristic, rather agreeable and refreshing odor, and a very bitter taste. It contains about one per cent. of a peculiar *essential oil* of a greenish-yellow color, bitter, burning taste, and sp. gr. 0.92, an amorphous hygroscopic, bitter substance, *tanacetin*, soluble in alcohol and water but not in ether, and *malic* (tanacetic) *acid*. Tansy and its oil belong to the more poisonous group of aromatics (camphor, cedar, juniper, turpentine, etc.), producing in large doses vomiting, convulsions, coma, etc., and death. Half an ounce, and even a drachm, of the oil have proved fatal. It is rather frequently taken by women for menstrual irregularities and to produce abortion, which latter, however, it seldom accomplishes. It may be given for same purposes as camphor and turpentine, but has little practical value.

ALLIED PLANTS, ETC.—See CHAMOMILE.

W. P. Bolles.

TAPIOCA (*Tapioka*, Codex Med.). The starch of *Manihot Utilissima* Pohl. (*Jatropha Manihot* Willd.), Order, *Euphorbiaceæ*, the cassava or manioc plant of the West Indies, a native of Brazil, but cultivated as a food-plant in many parts of tropical America. It is a perennial, growing several feet high, with three-, five-, or seven-lobed, palmate leaves, and very large tuberous roots. These latter, which are the edible part, are loaded with starch. When fresh, some varieties, "bitter cassava," contain a bitter, poisonous juice (prussic acid) which is dissipated by washing, expression, drying, cooking, etc. The pulp, ground fine, pressed and dried, and then pulverized, forms cassava meal, which is made into cakes and eaten; the starch washed and dried over a fire, stirred so as to agglutinate into irregular, partly cooked lumps, is the tapioca of commerce. The uncooked starch, like arrowroot in appearance, sometimes called "Brazilian arrowroot," occasionally reaches us.

Tapioca is simply an amylaceous food and has no medicinal properties. For the starches in general and a picture of Tapioca-granules, see STARCH.

W. P. Bolles.

TAR. Tar is a well-known product of destructive distillation of the wood of coniferous trees. It is a peculiarly sticky, semisolid body, nearly black in color, and of a characteristic empyreumatic odor and taste. It is

of acid reaction and very complex composition. By distillation it separates into three portions: one, the acid fluid known as *pyroligneous acid;* One, an empyreumatic oil, called *oil of tar;* and the third, the familiar substance *pitch*. *Pyroligneous acid* contains as its main ingredient *acetic acid;* the *oil of tar* is made up of a considerable number of bodies—*hydrocarbons*—including *benzene, toluene, xylene, naphthalene, pyrene, chrysene, retene,* and *paraffins; phenols,* including *phenol* (carbolic acid), *cresol, guaiacol, creasol, phlorol, methylcresol,* and *pyrocatechin,* besides resins and other substances. *Pitch* consists essentially of the resinous ingredients of the wood. Tar dissolves in alcohol, ether, fixed and volatile oils, and in solutions of potassa or of soda. Water dissolves a small proportion only of the constituents of tar.

Tar partakes of the general medicinal properties of the aromatic hydrocarbons and phenols. It is inhibitory of bacterial growth, is locally mildly irritant and healing, and of a tendency to repress catarrh, and, taken internally, may possibly exert a feeble anti-catarrhal influence through transportation by the blood to the affected spot. Tar has been used locally as an application in skin disease; and, internally, for the relief of catarrhs and urinary affections. It is very much less used now than formerly, its strong odor and taste being objectionable features. Tar is officinal in the United States Pharmacopœia under the title *Pix Liquida*, Tar. For internal administration an official *syrup of tar* is convenient. For the making of this syrup a portion of tar is first washed with cold water, to remove the irritating acid ingredients, and is then treated with boiling distilled water. To the resulting solution, filtered, sugar is then added. This syrup may be administered in teaspoonful doses or more. A *tar ointment* is also an officinal preparation of the United States Pharmacopœia, consisting of equal parts of tar and suet, mutually incorporated into a homogeneous mixture by effecting the mixing with the suet liquefied by gentle heat. This ointment furnishes a convenient means of making local applications of tar to the skin in cases of skin-disease. *Edward Curtis.*

TARASP, called also Tarasp-Schuls and Tarasp-Nairs, is an Alpine health-resort of growing popularity, lying in the Valley of the Inn, in the Lower Engadine, Canton Grisons (Graubündten), Switzerland. It lies at an elevation of about 4,000 feet above the level of the sea, and the climate is consequently cool, though not so cold as might be expected from the elevation, as the place is well protected against the north winds. There are several mineral springs here, of which the best known is the Luciusquelle. The following is the analysis of this water, according to Huseman. Each litre contains:

	Grammes.
Sodium bromide	0.0212
Sodium iodide	0.0008
Sodium chloride	3.6740
Lithium chloride	0.0030
Potassium sulphate	0.3797
Sodium sulphate	2.1004
Sodium borate	0.1722
Sodium nitrate	0.0008
Sodium bicarbonate	4.8788
Magnesium bicarbonate	0.9797
Ammonium bicarbonate	0.0661
Calcium bicarbonate	2.4497
Strontium bicarbonate	0.0007
Manganese bicarbonate	0.0003
Ferrous bicarbonate	0.0215
Phosphoric acid	0.0004
Silicic acid	0.0090
Clay	0.0002
Total	14.7585

There is a large amount of free carbonic-acid gas.

A second spring, the Emeritaquelle, is very similar to this in composition, but is less highly charged with carbonic acid.

The Ursus- and the Badequelle are also similar, but weaker in mineral constituents. These waters, used internally and in baths, are recommended in the treatment of catarrhal troubles of the digestive organs, hepatic disorders, gall-stones, obesity, and all congestive affections of the abdominal organs.

The Bonifacius-, Carola-, and Wyquelle are the chalybeate springs at Tarasp, the former containing about double the proportion of ferrous carbonate that is found in the Luciusquelle. They all contain a large amount of free carbonic-acid gas. These waters are used in the treatment of anæmia, debility, nervous disorders, and other conditions, in which a chalybeate tonic is indicated.

The season extends from the middle of June to the middle of September. The accommodations for guests are said to be good. *T. L. S.*

TARTARIC ACID. Tartaric acid, $H_2C_4H_4O_6$, takes its name from the substance which is its commercial source, namely, the material *tartar* that forms as an incrustation on the inside of wine-casks. Tartar is substantially an impure acid potassic tartrate, which salt by decomposition furnishes free tartaric acid. The acid is officinal in the U. S. Pharmacopœia under the title *Acidum Tartaricum*, Tartaric Acid, and is described as "nearly or entirely colorless, transparent, monoclinic prisms, permanent in the air, odorless, having a purely acid taste and an acid reaction. Soluble in 0.7 part of water, and in 2.5 parts of boiling alcohol at 15° C. (59° F.); in 0.5 part of boiling water and in 0.2 part of boiling alcohol; also soluble in 36 parts of absolute alcohol, in 23 parts of ether, and in 250 parts of absolute ether, and nearly insoluble in chloroform, benzol and benzin. When heated for two hours at 100° C. (212° F.), the crystals do not lose more than a trace in weight. On ignition, they should not leave more than 0.05 per cent. of ash" (U. S. Ph.). Tartaric acid is most often met with in the shops in the form of a white powder, tending more or less to cake into lumps.

Tartaric acid is a pleasantly flavored, sour, so-called organic acid, and in considerable quantity in strong solution is sufficiently irritating to cause dangerous and even fatal irritant poisoning. Several cases of death by tartaric-acid poisoning are on record, and in one of these half an ounce of the acid was the fatal dose. Tartaric acid being cheaper than citric, is often used as a substitute for that acid in the making of artificial lemonade. A six per cent. aqueous solution of tartaric acid may be regarded as the equivalent, in acid strength, of good lemon-juice, and a tablespoonful of such a solution may be used, like lemon-juice, by dilution with sweetened water for the making of an acid draught. A drop or two of essential oil of lemon, triturated with the dry acid before solution, improves the flavor of the draught. Tartaric acid is the acid used in the officinal formulæ of the U. S. Pharmacopœia for the making of effervescent preparations. *Edward Curtis.*

TASTE, THE SENSE OF. The chief organ of the sense of taste is the mucous membrane of the dorsum of the tongue, although, to a less extent, that covering the soft palate, the uvula, and the velum palati is capable of receiving gustatory impressions.

The special nerves presiding over the sense of taste are the glosso-pharyngeus for the posterior third, and a branch of the chorda tympani for the anterior two-thirds of the tongue. The nerves of common and tactile sensation are the glosso-pharyngeal for the posterior, and the lingual branch of the fifth for the anterior two-thirds.

However, this point is far from being definitely settled, some physiologists claiming that the lingual branch of the trigeminus, instead of the chorda tympani, is the gustatory nerve; others, that the only nerve of taste in the tongue is the glosso-pharyngeus, with which the specific nerves of gustation in the anterior two-thirds, after a circuitous route, ultimately unite.

The weight of evidence, both pathological and experimental, seems to be on the side of those who consider the chorda tympani and the glosso-pharyngeus as special nerves.

That the fibres of the chorda tympani terminate in the mucous membrane of the tongue is unquestionably a fact, since, as Vulpian has proved, degenerated nerve-fibres are found in this region after cutting that nerve.

The dorsum of the tongue is covered with stratified epithelium and beset with a number of papillæ of various forms and sizes, richly endowed with vessels and nerves. These papillæ are known as the filiform, fungiform, and circumvallate papillæ.

The filiform papillæ are principally found in the anterior two-thirds of the tongue. They are slender excrescences of the mucous membrane, slightly recurved and beset with epithelia, somewhat after the fashion of inverted ears of wheat. In the feline tribe these epithelia undergo cornification, which enables the animals to use the tongue as a rasp for the separation of the flesh from the bone.

FIG. 3750.—Isolated Cover-cells, from the Taste-buds of the Rabbit. × 600. (From Stricker.)

Probably they are not concerned in taste, but simply serve the purpose of common sensation.

The fungiform papillæ, from one hundred and fifty to two hundred in number, are round, knob-like expansions of mucous membrane, set on short, thick pedicles. They consist of a number of single papillæ and are distributed all over the tongue.

The circumvallate papillæ, numbering about nine or ten in man, are arranged in a V-shaped manner at the base of the tongue. They are elevations of the lingual mucous membrane, bearing on their flattened top numerous stunted papillæ, and are surrounded by a rim, a narrow deep fossa intervening.

Between the epithelia covering the slopes of the circumvallate papillæ and those of the inside of the circular ridge, occasionally also on the fungiform papillæ, peculiarly shaped flask-like bodies are met with, the taste-goblets, or taste-buds, so called from their forms. There are many reasons for looking upon these as being the terminal apparatus of the nerves of taste, notwithstanding that they have also been found on the posterior surface of the epiglottis, which certainly is not concerned in gustation. They are more numerous on the slope of the papilla than on that of the rim, and sit with a broad, rounded extremity on the limiting membrane. They consist of two kinds of cells—the outer, which are fusiform and joined together after the fashion of the leaves of a bud, and the inner, about four or five in number, which are long, slender cells, terminating at both ends in long protoplasmic rods, and containing in their centre a large, shining nucleus. They project slightly through an opening of the investing cells, the gustatory pore.

Although their connection with nerve-filaments has never been clearly made out, it is highly probable that they are analogous to the similarly shaped cells concerned in olfaction, to the rods and cones of the retina, etc.

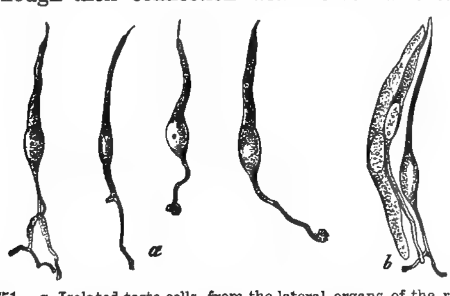

FIG. 3751.—*a*, Isolated taste-cells, from the lateral organs of the rabbit; *b*, a taste-cell and two cover-cells, isolated in a connected condition, from the same source. × 600. (From Stricker.)

At the bottom of the fossa open a number of convoluted tubular glands, secreting a serous fluid during gustation. The object of this secretion seems to be partly to dissolve the sapid substances, partly to wash them away after having been tasted, and thus prepare the terminals for fresh gustatory impressions.

The glosso-pharyngeal nerve-fibres serving common tactile sensation terminate after the fashion of the nerves of the epithelial layers of the cornea and skin; *i.e.*, they end by minute knobs in the cement substance of the epithelia. This manner of nerve termination obtains also in the anterior two-thirds of the tongue, where no special tasting organs are found, and where the nerve-fibres of special sensation terminate, like those of common sensation, between the epithelial cells.

Unlike the olfactory sensations, which cannot be classified, the various kinds of taste are generally divided into salt, sweet, sour, and bitter. These qualities of taste correspond in general to certain chemical groups; thus the salt taste is peculiar to the neutral soluble salts of the alkalies; the sweet, to the poly-atomic alcohols (glycerine, grape-sugar, etc.), which have, as a rule, a sweet taste; the sour to the acids; and the bitter to the alkaloids.

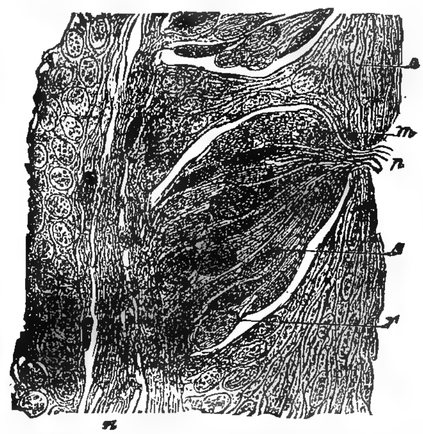

FIG. 3752.—Longitudinal Section of a Taste-bud. *p*, Gustatory pore; *s*, taste-cell; *r*, supporting cell; *m*, migratory cell, containing fat granules; *e*, epithelial cells; *n*, afferent nerve. (From Ranvier.)

There are an infinite variety and an unlimited number of shades of these four fundamental tastes, but the nicer distinctions, in what is generally called the taste of different substances, are made out by olfaction rather than by gustation. Every substance which has a taste has also a flavor.

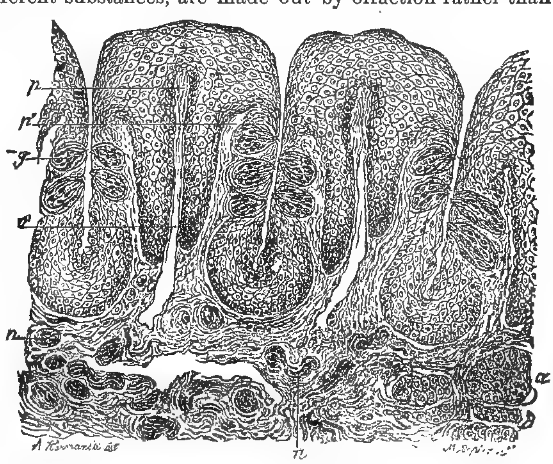

FIG. 3753.—Longitudinal Section of Papillæ Foliatæ of the Rabit. *p*, Central vascular tuft; *v'* transverse section of the central vein of the papilla; *p'*, nervous tuft or papilla; *g*, taste-bud; *n*, *n*, sections of afferent nerves; *a*, serous gland. (From Ranvier.)

The dorsal surface of the tongue does not perceive all the fundamental tastes equally well in all its parts. The sweet is best tasted with the tip, the sour at the edges, the bitter on the posterior third of the tongue. A cat whose glosso-pharyngeal nerves have been cut is said to drink without reluctance milk containg quinine.

Water and alcohol are tasted equally in every part of the dorsal mucous membrane; possibly these fluids give rise only to general sensations, and are not perceived by the special nerves.

The intensity of taste depends on the area to which the sapid substance is applied, on the degree of concentration, and on the temperature. The taste is best perceived of substances registering about 95° F. The interval between the application and the perception of the several sapid substances differs considerably; salt is tasted the most quickly.

In the same manner as colors become more dull when gazed at intently, and as odorous substances (perfumes or flowers, for instance) when smelled too long are no longer perceived, or may even give rise to disagreeable sensations, so the same food, especially when very savory, tasted continually, will exhaust the gustatory apparatus, and become insipid, or even distasteful.

It is not exclusively the sapid substances that give rise to gustatory sensations; a smart tap on the tongue with a small instrument (a lead-pencil or piece of whalebone, for instance) will produce a taste which is not, however, very definite, and is differently classified by different individuals. A fine current of air striking the tongue gives the impression of salt; the continuous electrical current, that of an alkali. The interrupted current does not produce any particular taste. I have found, however, that there are many individual variations in this matter. Thus, some persons distinguish between a bitter, metallic taste at the anode, and an acid one at the cathode.

The senses of touch and of temperature, which are very acute in the tongue, especially at the tip and on the edges, enable that organ to execute the many delicate and complicated movements which form part of its functions.

Hallucinations of taste are, like those of smell, of not unfrequent occurrence in the nervous and insane. The ideas of poisoning in the latter are probably always associated with such hallucinations. They depend on irritation and perverted function of the psychogenic centre, which lies in close proximity to the olfactory centre.

L. Bremer.

TATE EPSOM SPRING. *Location and Post-office,* Tate Spring, Grainger County, Tenn.

Access.—To Morristown by the East Tennessee, Virginia & Georgia Railroad, thence by carriage, ten miles, to the spring.

Analysis.—One pint contains:

	Grains.
Carbonate of lime	2.695
Chloride of sodium	5.033
Chloride of iron	0.365
Chloride of manganese	0.086
Sulphate of potassium	0.192
Sulphate of sodium	1.062
Sulphate of magnesium	3.996
Sulphate of lime	20.082
Phosphate of lime	0.142
Iodide of sodium	traces
Silica	0.337
Nitric acid	0.002
Total	33.992

Therapeutic Properties.—This is a very valuable calcic water, containing sufficient carbonic acid gas to render it very agreeable to the eye and to the taste. It is used with success as an alterative.

The spring is located in Beau Station Valley, at the southern base of Clinch Mountain, in the northeastern portion of Tennessee, at an altitude of 1,400 feet. The fact that it is situated amid the Cumberland and Alleghany Mountains insures grand scenery and pure air. The surrounding country affords fine hunting and fishing. The hotel and cottages are surrounded by a well-shaded lawn. *G. B. F.*

TATTOOING OF THE CORNEA. It has long been known that living animal tissues could be permanently colored by introducing into their substance finely powdered material, non-irritating in its character, that was itself insoluble or was capable of entering into insoluble composition with the tissues themselves.

Apart from purposes of savage decoration and the marking of criminals and prisoners for identification, this knowledge has not been particularly useful to the human race until a very recent date, when De Wecker, of Paris, gave it its recognized place among the expedients of ophthalmic surgery for the covering up of deformities, and occasionally for the improvement of the optical condition of the eye.

It was De Wecker's original intention merely to conceal or to render inconspicuous the unsightly scars, leucomata corneæ, that, when left on the cornea, as the result of injury or ulceration, are especially noticeable on account of their brilliant white appearance in the place where the darker coloring of the pupil and iris is generally seen, and where it often remains in sufficient amount to heighten by contrast the effects of the injury.

Several successful operations of this sort having been done, it was noticed that in some there was an improvement in vision as well as in personal appearance. This improvement, it was supposed, was caused in part by the narrowing of available pupillary area, and in part by the cutting off of that portion of the light which passed into the eye through the bright but irregular scar, thus having in some measure the optical effect of a stenopaic slit.

From these facts De Wecker was led to prophesy for tattooing a more brilliant future than it has since realized, and to think that it might come to be a supplementary operation to those cataract-extractions in which an iridectomy had produced a pupil too large for the best optical effects. The operation is seldom undertaken, however, except for cosmetic effect, and when done for that purpose it occasionally gives very gratifying results.

The substance most frequently used is India ink. That of the best quality should be selected. It is composed of fine lampblack united with a small amount of glue, so that the particles will be held in suspension by the water, which is ordinarily used as a menstruum. Mr. Charles Bell Taylor, of London, in order to obtain the deepest coloring, employed a mixture of India ink, fine lampblack, and nitrate of silver, and used sepia or ultramarine when the color of the iris made it desirable.

De Wecker operated with a lance-shaped knife having a groove on one side to hold the ink, which was made into a thick solution by the addition of water. From five to ten punctures were made at one time by pushing the knife obliquely into the superficial layers of the opaque cornea. These punctures were made as near together as possible, and it was sometimes necessary to repeat the operation five or six times before the desired result could be obtained. Later, multiple punctures were made by the use of seven needles held together in one bundle. There is not so much advantage in the use of the bundle of needles as would at first appear. It takes, of course, seven times the impact to penetrate the tissues with seven needles as with one, and thus more violence is done, while the punctures are more likely to be made in a perpendicular direction than when a single instrument is used. Probably as good an instrument as any for practical use is a fine steel writing pen, the point of which has been sharpened on an Arkansas stone.

To perform the operation the eye should be held open with a speculum and steadied with fixation forceps. Some absorbent, like cotton or sponge, should be held in contact with the lid or the periphery of the globe to drain away the tears as they are formed, so that they shall not wash away the coloring matter as fast as it is applied. It has been found best to work from above downward, so that the overflow of pigment shall not obscure the work as it progresses. The effect of the operation is probably increased by rubbing the pigment over the corneal surface with the end of the finger, so that it shall be well packed into the punctures made by the instrument. When the operation is complete the eye should be allowed to dry for a few minutes before the speculum is removed and the tattooed surface exposed to the action of the tears and lids.

The reaction after this operation is usually very slight,

and the improvement in the appearance is often remarkable; still, it is necessary to remember that many eyes in which the cosmetic effects of tattooing would be desirable are such as will not admit of any unnecessary disturbance, however slight; and where synechiæ exist that have proved themselves to be a source of continued disturbance, or where an irido-cyclitis, a glaucoma, or other destructive process has been going on, this operation is hardly advisable. *W. S. Dennett.*

TAYUYA. The root of *Dermophylla pendulina*, a Brazilian drug introduced a few years ago as a remedy in syphilis, scrofula, etc., has not taken any hold in practice in this country, and is probably without value, at least for the purposes named. It appears to be emetic and cathartic, having properties similar to bryony and other drastic *cucurbitaceæ*. From three to six drops of a ten per cent. tincture is said to be the dose.

W. P. Bolles.

TEETH. DENTAL ANATOMY.—The teeth are commonly divided into two sets, according to the period of their eruption. The teeth which erupt first are variously designated as the deciduous, the temporary, the milk, or the primary teeth. The teeth erupting subsequently to the first set are called the permanent or secondary teeth. In addition to these there are supernumerary teeth, which usually occur in connection with the permanent, but may, in rare instances, be found with the temporary teeth; and there are so-called third dentitions, the genuineness of which, though fairly well established, is not without question.

The permanent teeth are thirty-two in number, sixteen being placed in the upper, and sixteen in the lower, jaw. In each jaw there are four incisors (two central and two lateral), two canines, four bicuspids, and six molars.

A formula to express the number of the various teeth in each jaw is written as follows: I $\frac{4}{4}$, C $\frac{2}{2}$, Bic. $\frac{4}{4}$, molars $\frac{6}{6} = 32$.

The teeth of the upper jaw are symmetrically arranged along the alveolar margin of the superior maxillary bones. When viewed from below, their crowns are found to describe a parabolic curve. This curve, however, varies according to nationality, heredity, and accidental circumstances. The teeth of the lower jaw are arranged along the alveolar margin of the inferior maxillary bone, and their crowns describe a curve similar to that found in the upper jaw. This curve, however, is more pointed in front and more divergent behind. Speaking roughly, the masticating surfaces of the teeth of each jaw lie in a single plane, no crown projecting in a marked way beyond its neighbor. The teeth, also, when normally arranged, show no gap in the row, each tooth thus by its position giving and receiving support. In both these respects human teeth contrast strongly with those of the lower animals. In these it is common to find that certain teeth, as the canines in the carnivora, present a marked elongation, and also that between the teeth there occur intervals which allow of their interlocking.

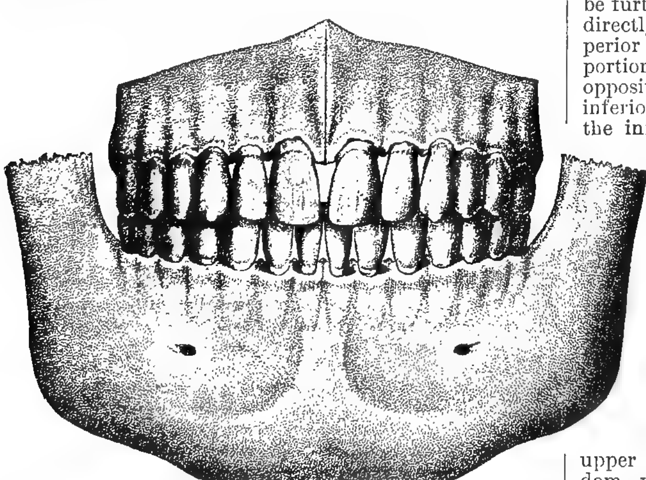

FIG. 3754.—The Permanent Teeth, natural size, showing their method of arrangement and articulation. (Carabelli.)

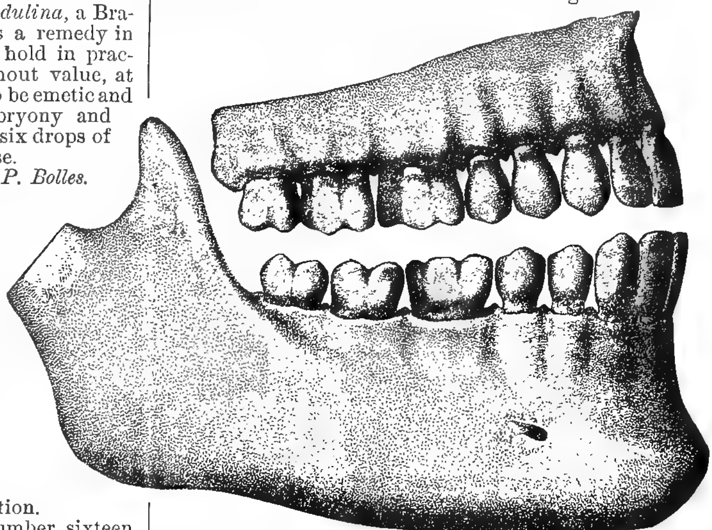

FIG. 3755.—The Permanent Teeth, natural size, showing the curves in the alignment of the crowns. (Carabelli.)

The curve on which the upper teeth of the permanent set are arranged is normally somewhat larger than that of the lower teeth. In consequence, the anterior superior teeth overlap the anterior inferior teeth, as do also to a slight extent the superior bicuspids and first and second molars the corresponding lower teeth. The wisdom teeth, however, meet practically edge to edge. It is to be further noted that the superior teeth are not situated directly opposite corresponding inferior teeth. The superior centrals are opposite the inferior centrals and a portion of the inferior laterals; the superior laterals are opposite a part of the inferior laterals and a part of the inferior canines; the superior canine occludes between the inferior canine and the first inferior bicuspid; the first superior bicuspid occludes between the first and the second inferior bicuspids; the second superior bicuspid occludes between the second inferior bicuspid and the first molar; the first superior molar occludes with the first and the anterior portion of the second inferior molar; the second superior molar occludes with the second and the anterior part of the third inferior molar; the third superior molar occludes with the third inferior molar, and is the only tooth in the upper jaw having a single antagonist. While it has been stated that the masticating surfaces of the teeth of the upper and lower jaws are on a single plane, yet slight deviations from this rule are to be noticed. If we follow the lower edge of the upper teeth from a superior central around to the wisdom, we shall find that the line ascends gently from the central to the interval between the first and second bicuspids, then descends till past the first molar, when it ascends slightly to the end of the row. On the lower jaw the anterior teeth are slightly elevated above the posterior, and between the canine and the wisdom tooth a slight concavity is to be observed.

In its description a tooth is to be divided into a crown, a root or fang, and a neck. The crown of a tooth is that part which normally appears beyond the margin of the

gum. The root or fang is that part which is normally embedded in the alveolus of the maxillary bone. The neck is a more or less constricted belt lying at the margin of the gum where the crown joins the root. The surfaces of the crowns are thus designated. Those surfaces lying adjacent to the lips are called labial surfaces, those lying adjacent to the buccinator muscle are called buccal surfaces. Those surfaces on the inner side of the teeth lying adjacent to the tongue are called lingual surfaces. In the case of the upper bicuspids and molars, however, such surfaces are more commonly called palatal surfaces, from their relation to the hard palate. The grinding surface of the bicuspids and molars is called the coronal surface. The surfaces between adjoining teeth are called approximal surfaces, and are divided into two classes—mesial and distal. The mesial approximal surface of a given tooth is that surface which, were the row of teeth in a straight line, would face toward a line drawn between the central incisors. The distal approximal surface is the corresponding surface at the opposite side of the tooth. These names are, as a rule, applied to the crowns of the teeth, though they are, with the exception of the term coronal, used also in connection with the roots.

Description of Individual Teeth.—The upper central incisor, so called from its chisel-shaped cutting edge, is the most noticeable tooth in the front of the mouth; its crown is wedge-shaped, and is bounded by four surfaces, which are, in a general way, triangular. The anterior triangular surface has for its base the cutting edge of the tooth, its apex lying at the margin of the gum. The anterior surface is convex from side to side, and also from above downward. The posterior surface is opposite the anterior, and, like it, is of triangular shape; the base of the posterior triangle unites with the base of the anterior triangle at the cutting edge of the tooth, while their apices are separated by the antero-posterior thickness of the root. The posterior surface is concave from above downward, and slightly concave or flat from side to side. A prominence can be noticed in the posterior plate near the gum, which is often accompanied by a pit situated at its lower base. Slight ridges run from the lower corners of the tooth posteriorly, and unite with this prominence at the margin of the gum. The cutting edge formed by the union of the anterior and posterior plates has three well-marked tubercles, which, however, are to be seen only in the newly erupted tooth, the friction of mastication soon wearing them away. In connection with the three tubercles on the cutting edge are necessarily two depressions, from which, in many cases, start shallow vertical grooves along the anterior surface of the crown. The lateral surfaces of the crown are triangular, the bases of the triangles being toward the gum and the apices at the cutting edge. The lateral surfaces always show a departure from a perfect triangular form, in having a notch in the base line caused by the encroachment of the cementum of the root upon the enamel of the crown.

The lateral surface toward the median line is convex from above downward; and slightly convex or flat from side to side. Its union with the anterior and posterior plates at the cutting edge forms the lower mesial angle of the crown, which is slightly acute. The distal lateral plate resembles in contour the mesial plate, except that it is more convex from side to side. It helps to form the distal angle of the cutting edge, which is obtuse and decidedly more rounded in contour than the mesial angle. The root of the upper central incisor is, roughly speaking, conical. Three distinct surfaces may, however, be described, one anterior and two lateral, which give to the root a triangular configuration. The anterior surface corresponds in position with the anterior plate of the crown, the two remaining surfaces correspond to the lateral and posterior plates of the crown. The root is much narrower posteriorly than anteriorly, and is thus able to adjust itself to the curve of the dental arch. The pulp cavity of the superior central is simple in form, and follows the external contour of the tooth; it is largest at the neck of the tooth, broad, but very shallow in the crown, and at the apex of the root is reduced to a thread. The neck of this tooth is situated high up anteriorly and posteriorly, but at the sides dips downward, forming a notch in the lateral plates.

The superior lateral incisor is situated at the distal side of the central incisor, and resembles that tooth in its general outlines, though it is much smaller in every dimension. The anterior surface of the crown is narrow and somewhat longer for its width than that of the central incisor; it is convex in both directions. The posterior surface of the crown is concave in its vertical measurement, and flat or slightly concave from side to side. A prominence can be noticed in the posterior plate at the margin of the gum, similar to that described as existing on the central incisor. This prominence is more marked than in the central, and indicates the development of a cusp, which attains its full proportions in the bicuspid teeth.

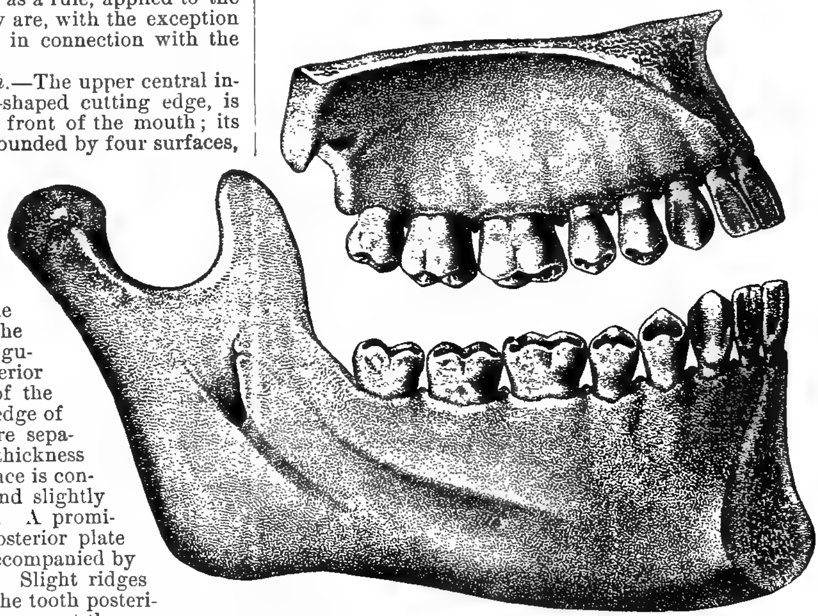

Fig. 3756.—The Permanent Teeth, Natural Size, Internal View. (Carabelli.)

The lateral surfaces of this tooth are convex, the mesial less so than the distal. The crown upon its cutting edge is marked, in the freshly erupted tooth, by three tubercles, as in the central incisor. Between the tubercles are two depressions, with which slight vertical grooves in the crown are connected. The inner angle of the crown at the cutting edge is slightly acute, while the distal angle is obtuse, the corner of the tooth being rounded off to a greater extent than the similar angle of the central. The root of the superior lateral is irregularly conical in shape. It is decidedly more flattened at the side than is the root of the central; it is broadest in front, and is bevelled slightly toward the posterior surface. The pulp-cavity is simple, following the outline of the tooth.

The superior canine is so called because it corresponds to the most prominent and characteristic tooth in the dog. It is also named the cuspid from having a cusp or point at the cutting edge. Popularly it is called the eye-tooth, from its location with reference to the eye. The canine, situated by the side of the lateral, is important in forming the contour of the face, while from its size and strength it is especially fitted for service in mastication.

The crown differs in a marked way from that of the incisors. Instead of its cutting edge being chisel-shaped it is pointed, and thus fitted to pierce rather than cleave. It is easy to trace the development of the crown of the canine from that of the freshly erupted central incisor. As stated above, the newly erupted central has three tubercles on its cutting edge. If the median tubercle is decidedly enlarged, while the lateral tubercles are nearly obliterated, and if, at the same time, the eminence described on the posterior plate of the central incisor be exaggerated, we have substantially the true form of the crown of a canine tooth. The anterior surface of the crown is convex, as are also the lateral surfaces. The posterior surface is concave from above downward, and flat or slightly convex from side to side. The prominence at its upper margin is marked, and is connected with the point of the cutting edge by a slight ridge. This prominence is also connected by similar ridges with the mesial and distal angles of the crown. The distance from the cusp to the mesial angle is less than from the cusp to the distal angle. By this means a right canine can be distinguished from a left. The root of the upper canine is longer than that of any other tooth, and gives rise to a marked ridge in the maxillary bone, associated with a marked depression called the canine fossa. The root, though more or less conical, is flattened laterally and bevelled away from front to back. This bevelling is necessitated by the position which a canine holds, at a decided curve in the dental arch. Slight longitudinal grooves are found at the sides of the root, which indicate a transition to a bifurcated or multiple root. The pulp-cavity is simple in shape and follows the exterior contour.

In passing from the canine to the bicuspid, the shape of the tooth is decidedly changed. According to comparative anatomists there are, in the typical dental formula, four bicuspids on each side of both jaws; and the sharp transition in the human species from the canine to the bicuspid is explained by inferring that the first two bicuspids are absent, and that those present are really the third and fourth, which are therefore somewhat removed in shape from the canine tooth.

The first upper bicuspid, also called the first premolar, has a crown which is rectangular in shape, having a long dimension from within outward and being narrow from front to back. The crown is surmounted by two cusps, hence the name bicuspid; one cusp is external and one is internal. The external cusp is longer and broader than the internal; its outer surface is convex and is continuous with the external plate of the crown. Its coronal surface is convex from side to side, and likewise from above downward. The line from the apex of the cusp to the mesial side of the crown is shorter than the line from the apex to the distal side. The internal cusp is similar in shape to the external, and is connected with it by an anterior ridge which unites the bases of the external and internal cusps along the mesial edge of the crown, and by a posterior ridge which unites the bases along the distal edge of the crown. Between the two cusps is a valley into which the sides of the cusps

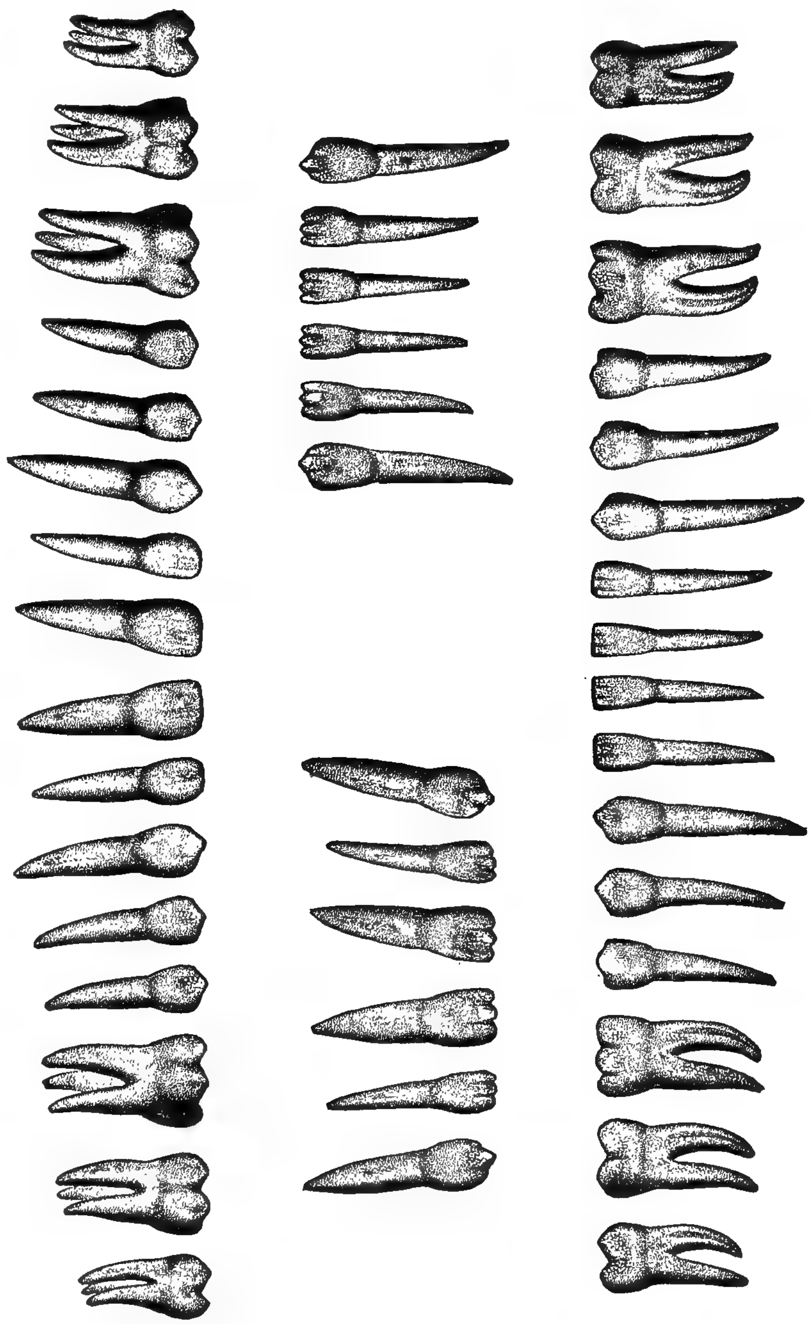

FIG. 3757.—The Permanent Teeth, Natural Size, showing the Labial and Buccal Surfaces. The middle row of teeth represents freshly erupted incisors and canines, with the tubercles on their cutting edges intact. (Carabelli.)

slope. The mesial and distal sides of the crown are convex, especially near the grinding surface, where prominences are developed for contact with adjoining teeth. The neck of this bicuspid is much constricted from its mesial to its distal side. The root is quite long, and is much flattened on its mesial and distal sides, displaying deep vertical grooves; in fact, it is often bifurcated near the extremity. The pulp-chamber is quite narrow from before backward, and is prolonged in the direction of each cusp; in the root it is usually compound, being divided into two compartments by the longitudinal constriction of the root.

The second upper bicuspid, situated behind the first, resembles it in shape. It may be distinguished from it, however, by its root, which is less flattened, thicker from the mesial to the distal surface, and does not tend to bifurcation near the apex. Its pulp-cavity is usually single.

The first upper molar, situated behind the second bicuspid, is the most bulky tooth in the mouth; from its size it plays an important part in giving fulness and ex-

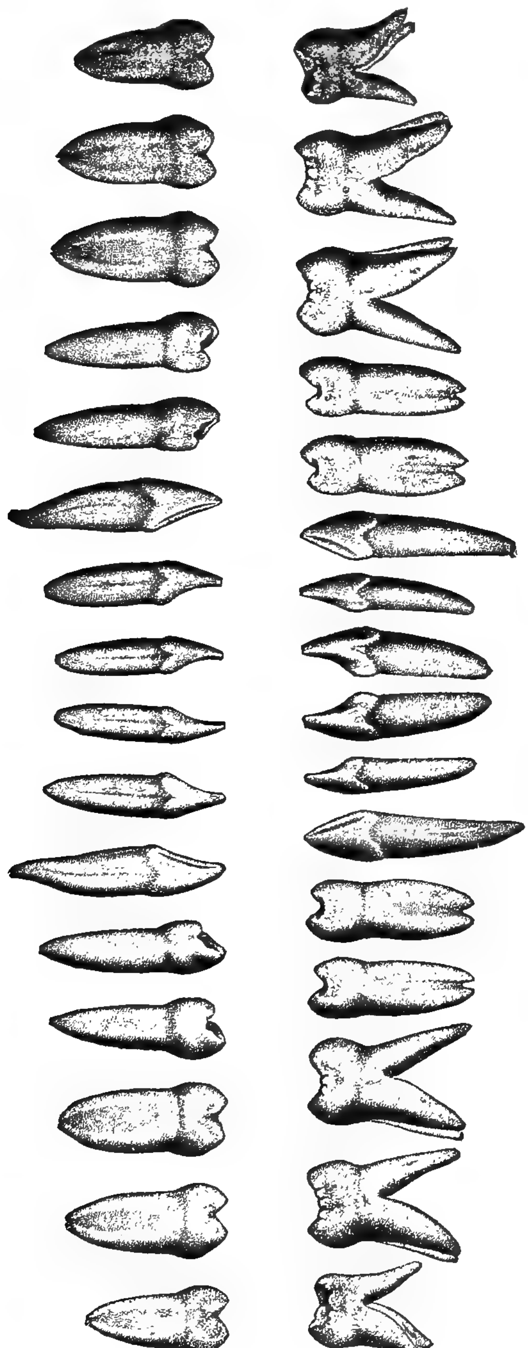

FIG. 3758.—The Permanent Teeth, Natural Size, Side View. (Carabelli.)

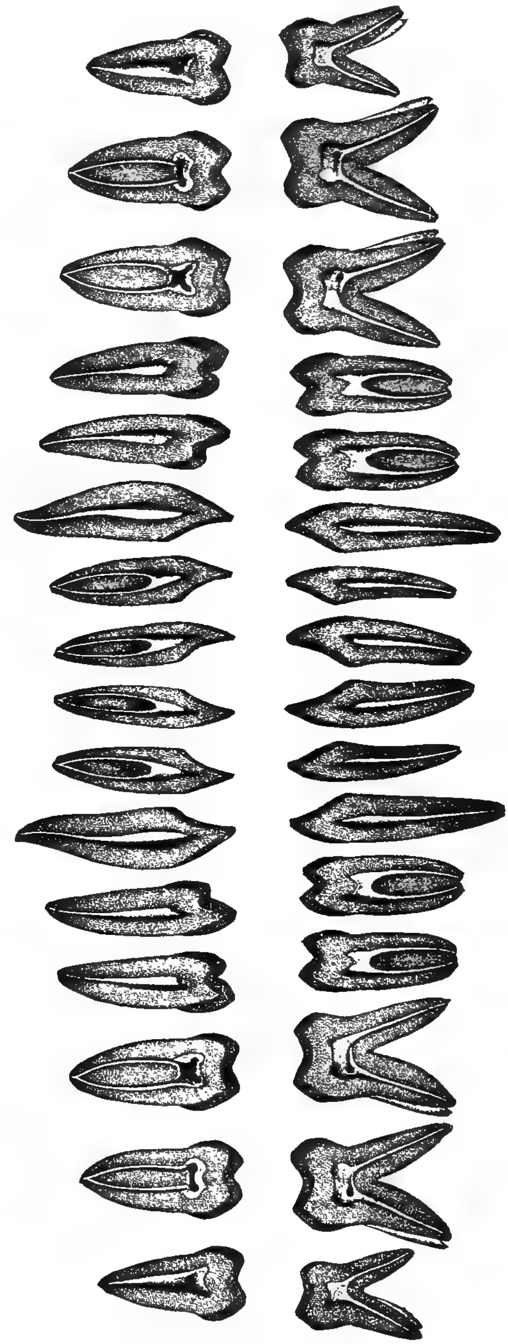

FIG. 3759.—The Permanent Teeth, Natural Size, a Section through the Pulp-cavity, showing its Size and Shape. (Carabelli.)

pression to the side of the face. Its crown is cuboidal in shape, and bears upon its grinding surface four cusps, which are situated at the corners of the cube—two externally and two internally. The external cusps are of about equal size, and are divided by a fissure which starts at the grinding surface and is prolonged vertically up the buccal side of the crown. From the anterior external cusp to the anterior internal cusp there exists a ridge which borders the mesial surface of the crown, and antagonizes with a similar ridge on the distal surface of the second bicuspid. The anterior internal cusp is the largest of the four; it is connected with the anterior external cusp by the ridge just described, and with the posterior external cusp by another, called the oblique ridge. The posterior internal cusp is separated from the anterior internal cusp by the oblique ridge and its valley; and is joined to the posterior external cusp by a ridge which bounds the distal edge of the crown. The roots of the first molar are three in number—two external or buccal, and one internal or palatine. The palatine root is the largest of the three, and underlies the two internal cusps. It diverges from the crown at a slight angle toward the palate; it is conical in shape, but has in many cases a vertical groove on its palatine side, which hints at a division into two roots. The two external roots underlie the anterior and posterior external cusps respectively; they are broader upon the external surface than upon the internal, and diverge lightly outward from the crown, and also from each other. The anterior buccal root is larger in every dimension than the posterior. The pulp-cavity is complex, occupying the three roots and extending into the four cusps of the crown.

The second upper molar, situated behind the first, is similar to it in shape. It is, however, somewhat smaller in all dimensions.

The third upper molar, or wisdom tooth, is situated behind the second molar. In some cases, where a roomy jaw exists, it resembles closely the second molar in shape. As a rule, however, it is imperfectly developed. Its crown is much smaller than that of the second molar, and has three cusps instead of four, two external and one internal. Its root, formed by the confluence of three roots, is through most of its length single, but at the tip usually separates into three. The direction of the root is backward and outward. The pulp-cavity is small, and in the root tends to a threefold division.

The teeth of the lower jaw, though they in general resemble the corresponding teeth of the upper jaw, present many differences. The lower central incisor is much smaller than the upper central incisor; its crown is chisel-shaped, being convex in front, and flat or slightly concave behind. The angles formed by the cutting edge and the body of the crown are both acute, and substantially equal, thus differing from the upper central, whose distal angle is obtuse. The root is long and tapering, flattened on the sides, and slightly bevelled toward the posterior surface. Shallow vertical grooves may be seen upon the anterior face of the crown, similar to those described in the upper centrals. When newly erupted, both lower central incisors possess upon their cutting edges three tubercles and two intervening depressions, but these are soon lost through wear.

The lower lateral incisor is placed on the distal side of the central incisor; it resembles that tooth in shape, but is larger. It will thus be seen that the relative size of the inferior lateral and central incisor is the reverse of that of the superior lateral and central incisor.

The lower canine tooth follows the shape of the upper canine; its crown is, however, not so pointed as that of the upper canine, and its root is more slender. The cusp of the crown is directed somewhat inward, and is thus able to shut inside the teeth of the upper jaw.

The first lower bicuspid resembles in shape the upper bicuspids; its crown is, however, smaller, especially in the labio-lingual dimension. Of its two cusps, the outer is the larger, and is directed slightly inward; the inner cusp is often quite small, and only slightly larger than the rudimentary second cusp of the canine. The root is more conical than are the roots of the upper bicuspids, and, though somewhat flattened on the mesial and distal sides, does not tend toward a bifurcation.

The second lower bicuspid is situated behind the first. Its crown resembles that of the first, but is somewhat larger. The internal cusp is often divided by a slight notch into two cusps, thus indicating a development toward the multicuspid teeth which follow. The root is conical, but flattened on the mesial and distal sides; the pulp-cavity is single.

The lower first molar, situated behind the second bicuspid, is the largest tooth in the lower jaw. Its crown is quadrilateral in shape, and is surmounted by five cusps, three external and two internal. Of the five cusps the external posterior cusp is much the smallest, being oftentimes of rudimentary size. The two internal cusps are larger than the external cusps. A valley at whose bottom is a fissure separates the external from the internal cusps, and a lesser valley separates each cusp from its neighbor. As a rule, a well-defined crucial figure is formed by the fissures in the crown of this tooth. The longer fissure extends from the mesial to the distal side, and the shorter fissure from the buccal to the lingual side, of the tooth. Where the small buccal cusp is present the long fissure bifurcates at the centre of the crown, one branch passing between the second and third buccal cusps, and the main branch directly backward, between the posterior buccal and the posterior lingual cusp. The roots of the first molar, two in number, are situated, one beneath the anterior, and the other beneath the posterior, part of the crown. The two roots, starting from the under side of the crown, diverge from each other at an acute angle, while at the same time they both curve gently backward. The anterior root is much broader than the posterior; it is decidedly flattened from front to back, and has a vertical median groove along its anterior and posterior surfaces. In some cases this root is bifurcated along the line of these grooves, and two distinct roots take the place of the single one which exists normally. The posterior root is conical in shape, though more or less flattened from before backward. It does not tend to subdivision. The pulp-cavity is complex, the anterior root containing two very small root-canals, the posterior root, one single and ample canal.

The second lower molar is situated behind the first, and resembles it in its outlines, though of smaller dimensions. The crown often drops the small posterior buccal cusp and limits itself to four cusps, one on each corner of the crown, and separated by a crucial depression. The roots are smaller than those of the first molar, but have the same configuration and curve.

Fig. 3760.—A Lower Third Molar, with hook-shaped Roots. (Carabelli.)

The third lower molar, where plenty of room exists for its development, resembles the second molar in shape. As a rule, however, it is cramped for room, and becomes dwarfed. Its cusps are diminished to three, two buccal and one lingual. Its two roots are small, and to a large extent confluent. Their backward curve is much more decided than is that of the first two lower molars, and so great is it in many cases that the root resembles a hook, and is thus locked into the alveolus of the jaw.

The *temporary teeth* are twenty in number. In each jaw there are four incisors, two canines, and four molars. The dental formula is I $\frac{4}{4}$, C $\frac{2}{2}$, molars $\frac{4}{4} = 20$.

This formula differs from that of the permanent teeth by the entire absence of bicuspids, and by the loss of four molars. The temporary teeth can best be described by comparing them with the permanent teeth, which they closely resemble.

The incisors and canines of the upper and under jaws are very much smaller than the corresponding teeth in the permanent set, and the root of the upper central incisors is somewhat curved on the mesial side where the corresponding root in the permanent teeth is practically straight.

The first upper molar is situated behind the canine, and in appearance is a compromise between a bicuspid and a

molar. Its crown resembles in general shape that of an upper molar, but is quite small, and bears only three

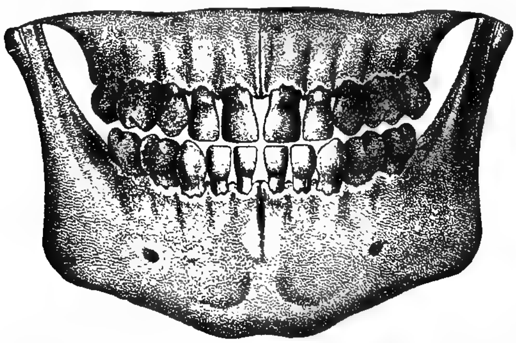

FIG. 3761.—The Temporary Teeth, Natural Size, showing their Arrangement in the Maxillary Bones, and Relations to one Another. (Carabelli.)

cusps—two external and one internal. The roots are three in number, resembling in shape and position those of the permanent molars. They are, however, more divergent, thus providing room for the first bicuspid, whose crown is situated directly beneath the temporary tooth, and within the grasp of its roots.

The second upper molar is a much larger tooth than the first, and resembles so closely the first permanent molar that it might be mistaken for it. Its roots are more divergent, however, in order to embrace the crown of the second bicuspid, to which it gives way in the permanent dentition.

The first molar in the lower jaw is situated behind the canine, and resembles in shape a permanent molar of the lower jaw. Its crown is surmounted by four cusps—two external and two internal. It has two roots, one anterior and one posterior, between which is developed the crown of the first inferior bicuspid.

The second lower molar is larger than the first, and a little smaller than a permanent lower molar, which it closely resembles. Its crown has five cusps—three external and two internal. There are two roots, one anterior and one posterior, which embrace the developing crown of the second lower bicuspid. It is characteristic of the temporary teeth that the foramen at the apex of the roots is larger, that the necks of the teeth are more constricted, and the color whiter and more delicate than in the permanent teeth; also, that the six anterior upper teeth do not overlap the corresponding lower teeth to such an extent as in the permanent set.

FIG. 3763.—An Upper Temporary Molar, with a Bicuspid within the grasp of its Roots. (Wedl.)

MICROSCOPIC ANATOMY OF THE TEETH.—A longitudinal section through a tooth will reveal four distinct structures—the enamel, the cement, the dentine, and the pulp. The pulp is a soft mass of connective tissue richly supplied with blood-vessels and nerves, and located in the centre of the tooth. It fills the pulp-cavity. The pulp-cavity starts at the apex of the root or roots, as the case may be, as a thread-like canal, and gradually enlarges till it reaches the crown, where it attains its greatest size; throughout its whole course it imitates in shape the external contour of the tooth. An artery and nerve, and sometimes more than one of each, enter the apical foramen of each root of a tooth, and, branching freely, distribute themselves to all parts of the pulp, being especially abundant about its periphery. A venous system returns the blood through the apical foramen into the general circulation. It is a matter of dispute whether a lymphatic system is present or not; most observers consider that it is not. Around the periphery of the pulp, and distinct from the connective-tissue cells forming its body, there exists a layer of cells called the odontoblastic layer, or the membrana eboris. In shape these cells are large in comparison with the connective-tissue cells; they are of columnar form, and have several processes. By these processes they are united to the terminal filaments of the nerve of the pulp, joined to one another, and connected with the dentinal fibrils.

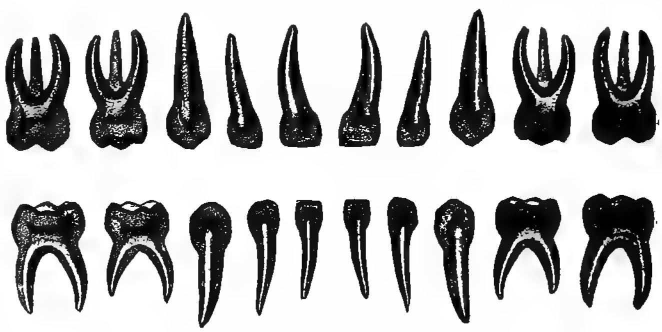

FIG. 3764.—The Temporary Teeth, Natural Size; a Section through the Pulp-cavity shows its Size and Shape. (Carabelli.)

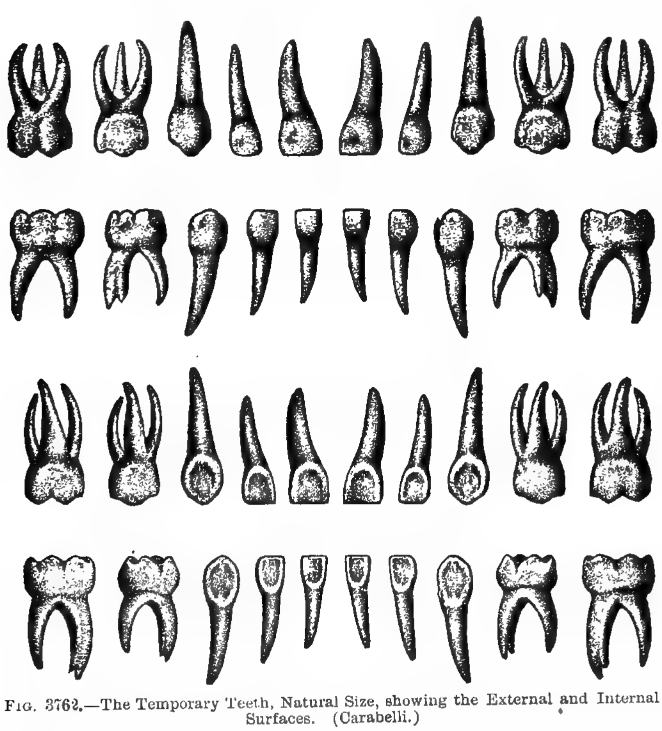

FIG. 3762.—The Temporary Teeth, Natural Size, showing the External and Internal Surfaces. (Carabelli.)

Immediately surrounding the pulp comes the dentine, which is the most abundant tissue of the tooth. It is hard and dense in structure, of a yellowish-white color and silky lustre. On analysis it is found to contain animal matter, twenty-eight per cent.; earthy matter, seventy-two per cent. Its various components are thus given by Von Bibra:

Organic matter	28.01
Phosphate and fluoride of calcium	66.72
Carbonate of calcium	3.36
Phosphate of magnesium	1.18
Other salts	.73
Total	100.00

Morphologically considered, it is composed of a structureless matrix permeated by countless

tubules, each tubule possessing a lining membrane and a central fibril. The tubules start from the pulp-cavity, where they have a diameter of about $\frac{1}{5000}$ of an inch, and radiate toward the periphery of the dentine, becoming smaller and more numerous as they advance. While the direction taken by the tubules in different parts of the tooth varies greatly, yet contiguous tubules are essentially parallel. Two or three undulatory curves are to be noticed in the length of a tubule, and the name primary curvature has been attached to them. Numerous spiral turns occurring in the course of the undulatory curves have been named the secondary curvatures. The tubules give off frequent branches throughout their entire length. Some of these branches are important, extending to the outer layers of the dentine parallel to the main channel. Other branches serve merely to connect one tubule with another, and still others are blind processes. At the outer layer of the dentine the tubules become diminished in size, and very numerous. Some of the tubules can be seen entering the granular layer of the dentine, while others either terminate blindly or anastomose with neighboring tubules. The "granular layer of Purkinje" consists of numerous irregular cavities filled with cells having nuclei, and forming a layer about the peripheral portion of the dentine, being especially well developed where the dentine is covered by the cement of the root. The cavities of this layer communicate with each other, and, in some cases, with the canaliculi of the cement, besides being connected with the tubules of the dentine. The tubules of the dentine have been shown to possess a lining membrane, and to this the name dentinal sheath has been applied. This structure resists the action of reagents which destroy the matrix in which the tubules are embedded, and is supposed to consist of elastic tissue, though its composition is not surely determined. The dentinal fibril which occupies the centre of the tubule is a soft homogeneous substance, having a nerve-like function, but lacking true nerve-structure.

The fibril is connected at one end with an odontoblastic cell in the periphery of the pulp, and the other end enters, in many cases at least, the granular layer of the dentine, coming into contact with the soft tissue there contained. Through the dentinal fibril communication is maintained with the nerves of the pulp, and sensation is supplied to all parts of the dentine. In longitudinal section of that part of the dentine which lies in the crown of the tooth are to be seen lines which are called the "incremental lines of Salter." They run, in general, parallel to the external contour of the crown, and mark stages in the development of the dentine, being not unlike the circular rings of wood-fibre, and are due to the presence of interglobular spaces. That the dentine is developed by stages is made apparent by treating it with hot caustic potash. By this reagent the dentine becomes separated into layers, which cross the tubuli at right angles, and are concentric about the pulp. In the crown of the tooth, between one layer of dentine and another, there occur imperfectly calcified spots where the dentine assumes a globular form, and where irregular interglobular spaces are found. Series of interglobular spaces give rise to the "incremental lines of Salter."

The dentine is surrounded in the crown by the enamel, and in the root by the cementum.

The cementum, or crusta petrosa, is the outer covering of the root. It is thinnest at the neck of the tooth, where it meets and slightly overlaps the enamel, and grows gradually thicker toward the apex, about which point it is most abundant and its structure is most perfectly developed. Cement has essentially bone-structure; it possesses lacunæ and canaliculi, but has normally no Haversian canals. The lacunæ and canaliculi are wanting or rare in that part of the cement near the neck of the tooth, but about the apex of the root they are numerous and well developed. The lacunæ lie in parallel planes encircling the pulp-cavity, their canaliculi anastomose freely with each other, and in some cases they connect with the granular layer of the dentine, thus establishing a communication between the lacunæ of the cement and the pulp of the tooth through the granular layer and tubuli of the dentine.

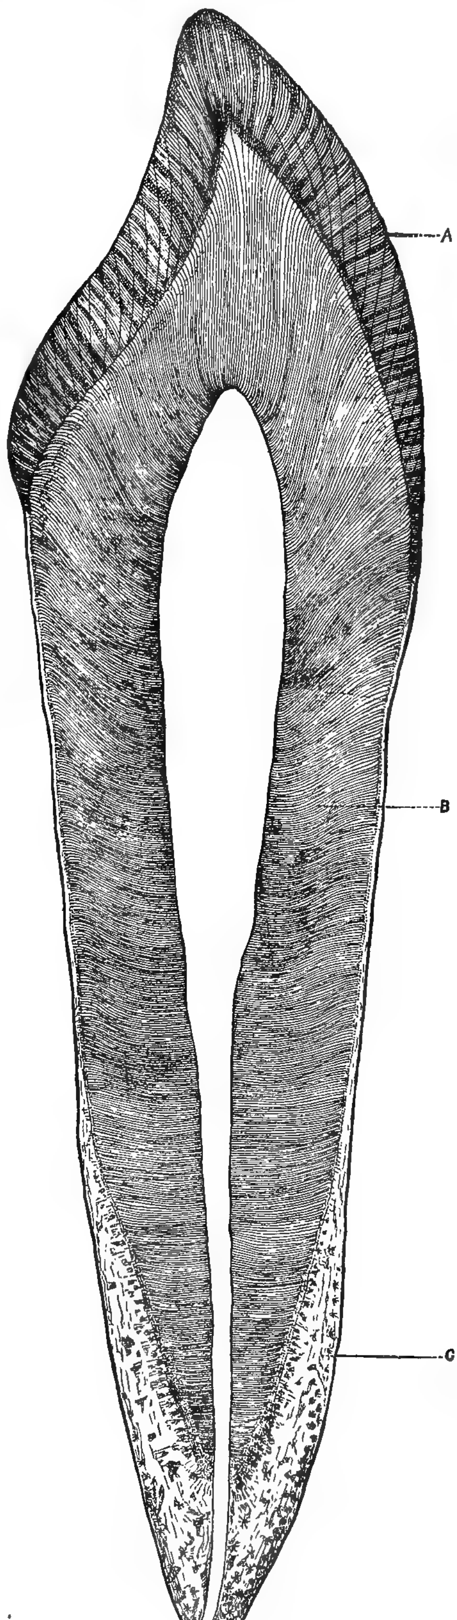

FIG. 3765.—A Microscopic Section of a Canine Tooth, showing, A, the enamel, with its enamel-rods running from the dentine to the outer surface. The dark stripes indicate places where the enamel-rods cross each other. The fine parallel lines are the "brown lines of Retzius." B is the dentine, with its tubules radiating from the pulp-cavity. The undulatory curves of the tubules are called the primary curvatures. The secondary curvatures are not visible at this enlargement. The granular layer is indicated by the dotted line about the periphery. It is especially marked between the cement and dentine, and practically absent between the enamel and dentine. The interglobular spaces are represented in the coronal portion of the dentine just removed from the junction of the dentine and enamel. C indicates the cement, with its lacunæ and canaliculi.

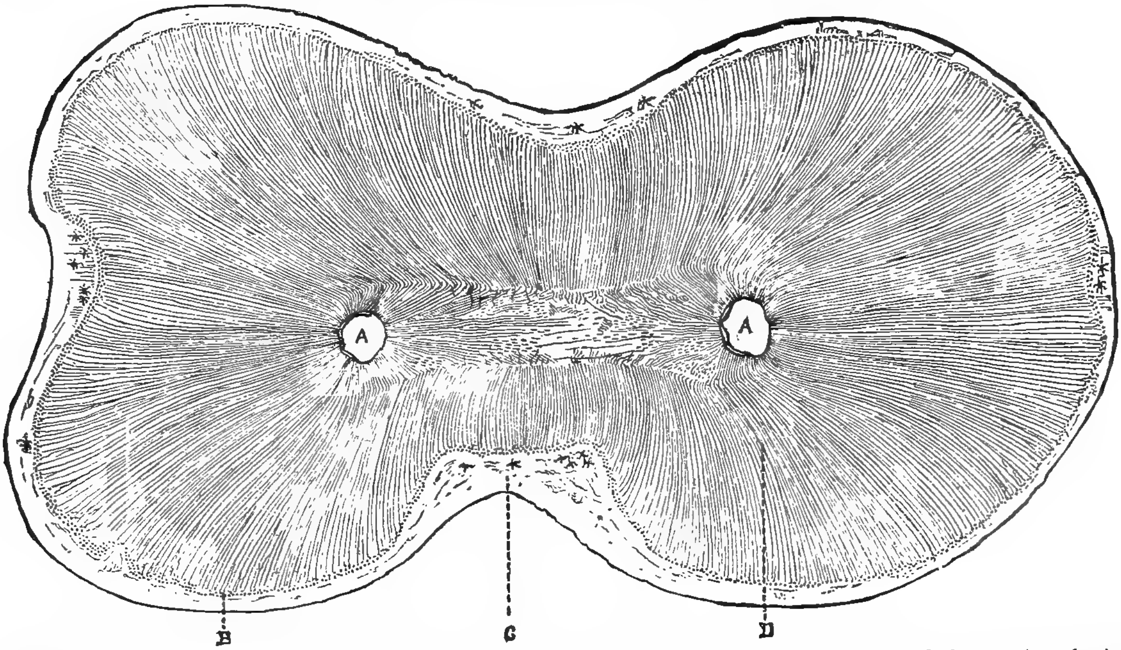

FIG. 3766.—Cross-section of an Upper Bicuspid Tooth. A, A, the root-canals; B, the granular layer of the dentine; C, the cementum, showing occasional lacunæ; D, the dentine.

Immediately surrounding the cementum of the root exists the peridental membrane, which is identical with the periosteum which lines the bone forming the socket of the tooth. The peridental membrane serves a triple function. It nourishes the bone of the socket and the cement of the root, besides forming a bond of union between the root and its socket. The peridental membrane, like all periosteum, is composed of connective tissue richly supplied with blood-vessels. The arterial supply comes from capillaries of the gum about the neck of the tooth, from the deep substance of the bony socket, and from a branch of the artery entering the apical foramen of the tooth.

The enamel forms the outer covering of the crown; it is the hardest structure in the body. It resembles dentine in its chemical constituents, but has a much greater proportion of inorganic material. The following analysis is given by Von Bibra:

Phosphate and fluoride of calcium	89.82
Carbonate of calcium	4.37
Phosphate of magnesium	1.34
Other salts	0.88
Cartilage	3.39
Fat	0.20
Total	100.00

The proportion of organic and inorganic matter is as follows:

Organic	3.5
Inorganic	96.5
Total	100.00

Morphologically considered, enamel is composed of rod-like, hexagonal prisms, arranged side by side, one end of the prism resting on the outer layer of the dentine and the other forming the free surface of the crown of the tooth. Each prism extends, as a rule, through the entire thickness of the enamel. There are some, however, which extend only from the centre of the enamel to its free surface, thus preventing gaps which would otherwise occur, the outer surface of the enamel being of greater extent than the inner. In diameter the enamel prisms measure $\frac{1}{5000}$ to $\frac{1}{7000}$ of an inch. Each prism, when isolated, has slight varicosities and presents a striped appearance similar to muscular fibre. The prisms run, in general, parallel to each other, and in a wavy course; their inner ends are implanted in slight hexagonal depressions in the surface of the dentine, and their outer ends are received into similar depressions in the under side of the cuticle of the enamel when the cuticle is present. A vertical section of the enamel shows that it is thickest in the crown, especially in the region of the cusps, and becomes thinnest at the neck of the tooth, where it is overlapped by the cement of the root. The enamel-prisms are seen to leave the outer surface of the dentine at right angles, and radiate toward the external surface of the tooth. The general yellowish-white color of the enamel is varied by dark bands extending vertically from the dentine to the free surface of the enamel, caused by the crossing of bundles of enamel-prisms. Certain delicate lines running longitudinally through the substance of the enamel are also to be noticed. These are called the "brown lines of Retzius," but

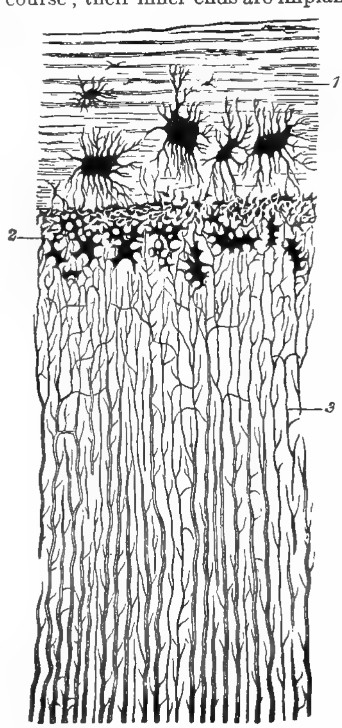

FIG. 3767.—A Section of Dentine and Cement. The figure 1 represents the cement with its lacunæ and canaliculi; the figure 2 represents the granular layer of the dentine. It is to be noticed that the lacunæ communicate with the cells of the granular layer. The figure 3 represents the tubuli of the dentine, showing their diminution in size as they go toward the cement, also their frequent anastomoses and their connection, in some cases, with the cells of the granular layer. (Quain.)

it is not known to what they are due. Also between enamel rods, usually near the surface of the dentine, are found irregular cavities due to an imperfect calcification of the enamel. On cross-section the enamel has the appearance of a mosaic pavement, each prism showing its hexagonal shape. The small amount of organic material which exists in enamel is deposited mainly between the prisms, forming a cement which binds them together. This cement is more abundant in young than in adult teeth.

The cuticle of the enamel, or Nasmyth's membrane, is to be found in a freshly erupted tooth. It consists of a delicate epithelial covering which encloses the enamel; it

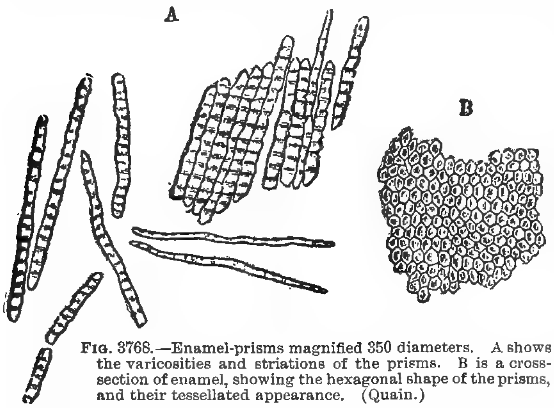

FIG. 3768.—Enamel-prisms magnified 350 diameters. A shows the varicosities and striations of the prisms. B is a cross-section of enamel, showing the hexagonal shape of the prisms, and their tessellated appearance. (Quain.)

is, however, so delicate that in the slightest use it is worn away. It receives in hexagonal depressions on its under side the outer ends of the enamel prisms.

TIME OF ERUPTION OF THE TEETH.—The first dentition begins about the seventh month, and is completed about the twenty-fourth month. The second dentition begins about the sixth year, and is completed about the twenty-first. Considerable variation exists in the time at which individual teeth erupt, and no date can be absolutely fixed for the appearance of a given tooth. It is possible, however, to state the time when the eruption of a tooth is normally to be expected, and the following tables are appended:

Temporary Teeth.

The central incisor erupts at the	7th month.
The lateral incisor erupts at the	9th month.
The first molar erupts at the	12th month.
The canine erupts at the	18th month.
The second molar erupts at the	24th month.

Permanent Teeth.

The first molar erupts at the	6th year.
The central incisor erupts at the	7th year.
The lateral incisor erupts at the	8th year.
The first bicuspid erupts at the	9th year.
The second bicuspid erupts at the	10th year.
The canine erupts at the	11th year.
The second molar erupts at the	12th year.
The third molar erupts at the	17th–21st year.

As a rule, in both the first and second dentitions the lower teeth erupt before corresponding teeth in the upper jaw.

PHYSIOLOGY OF THE TEETH.—Under this head we naturally consider the purposes for which teeth exist, and how they perform their several functions. The subject may be divided into three heads:

(1) The function of the teeth in facial expression. (2) The function of the teeth in mastication. (3) The function of the teeth in articulation.

The importance of the teeth in facial expression becomes apparent when we consider the effect of their absence, as shown in aged people. In such the lower part of the face has lost the round and graceful lines of early years; the chin is pointed, and approximates the end of the nose; the lips are retracted and flabby, and a characteristic hollow extends along the cheek. When present, each tooth aids in sustaining the proper proportions of the face. The upper front teeth, by being slightly in advance of the lower, produce that slight projection of the upper lip beyond the lower, found in normally shaped features. The bicuspids and molars, by their apposition, fix the relation of the lower to the upper jaw, and by their bulk give fulness to the cheeks. The bony alveolus, also, in which the teeth are embedded, has an important relation to facial expression, for when a tooth has been lost, its bony support, being no longer needed, is absorbed, and thus the features are still further deprived of support.

The function of the teeth in mastication is the most obvious and important. Standing as they do at the entrance to the digestive tract, it is their duty to seize upon food, sever its connection with its surroundings, and comminute it so that it can be acted upon readily by the various digestive fluids. The act of seizing and cutting is performed by the six anterior teeth, whose edges, by the protrusion of the lower jaw, are brought opposite to each other. When once a morsel of food has been detached by the anterior teeth, it is passed backward by the tongue and cheeks, to be operated upon by the bicuspids and molars. The bicuspids are fitted both to cut and to grind. They cut by the outer cusps of opposing teeth meeting and passing each other like the blades of a pair of scissors. They crush by a lateral motion, the crowns of the lower bicuspids moving across those of the upper. The function of the molar teeth is to crush and grind, for which purpose they are fitted by their broad crowns. They crush by means of an up-and-down movement, and grind by a lateral movement.

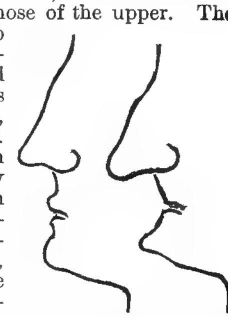

FIG. 3769.—The first profile represents the features undisturbed by loss of teeth. The second represents the edentulous condition, in which the lips fall in and the chin becomes pointed and inclined toward the nose.

The function of the teeth in articulation is best understood by a brief survey of the mechanism of speech. This mechanism includes the vocal cords, and a resonant cavity above the cords, formed by the pharynx and the oral and nasal cavities. This resonant cavity reinforces and modifies sounds made by the vocal cords. Articulation is concerned with sounds of two kinds—vowels and consonants. The vowels are musical notes formed by the vocal cords, and given quality or timbre by the size and shape of the air-column in the resonant cavities above. The consonants are sounds produced by the same mechanism, but due to irregular vibrations, and hence are noises. The oral cavity, being able to change its size and shape in numberless ways, is the most important agent in sound modification.

To produce articulate sounds the column of air must be obstructed and forced into channels of definite size and shape. The column of air is obstructed in three ways: first, by applying the back of the tongue to the palate; second, by applying the tip of the tongue to the posterior surfaces of the anterior teeth; and third, by a closure of the lips. It is forced into definite channels by pressing the tongue against different parts of the roof of the mouth, and against the inner surface of the upper teeth.

To produce the sound T, the tip of the tongue is placed against the posterior surface of the upper incisors, while the sides of the tongue touch the bicuspids and molars on both sides. With the tongue in this position a column of air is held under pressure and suddenly released through the front part of the mouth with an explosive sound. D is made in a similar way. F and V are made by bringing the lower lip against the under side of the upper incisors, the tongue meanwhile touching the inner surfaces of the upper second and third molars. A column of air is then forced out between the upper incisors and the lower lip. The letter S is sounded by nearly shutting the teeth and forcing the air between them, the tongue meanwhile being placed against the upper bicuspids and molars, and thereby narrowing the oral cavity to a slight channel along the roof of the mouth.

To pronounce Sh, the teeth are closed and the tongue is placed against the upper bicuspids and molars, leaving a narrow channel along the roof of the mouth. Along this channel a blast of air is forced which escapes between the front teeth with a hissing noise.

The agency of the teeth in the formation of the consonants is recognized by grammarians in their separation of the consonants into labials, palatals, and dentals. Although the teeth are important for perfect articulation, yet when lost they are to a great degree compensated for by an increased activity of the lips, cheek, and tongue. These parts so adapt themselves to the diminutive alveolar ridge which remains that fair articulation is still possible. What most seriously interferes with articulation is the loss of one or two of the front teeth while the others remain. In such a case the adjoining structures exercise their compensatory function with difficulty, and sounds depending for their formation upon the presence of the front teeth are not easily made. The loss of the back teeth is compensated for by the drawing in of the cheek and the bulging outward of the tongue. By this means it is possible to carry a column of air to the front of the mouth and prevent its escaping at the sides.

As a minor function of the teeth may be mentioned their tactile sense, by which, together with the muscular sense located in the muscles of mastication, the degree of hardness of bodies is perceived. This tactile sense of a tooth is dependent on the sensitive peridental membrane, which perceives and records the impact of the tooth against every substance.

Pathology of the Teeth.—*Pathology in the Number of Dentitions and their Time.*—While two is the normal number of dentitions, much can be heard and read of a third dentition, the authority for which, however, rests, as a rule, with unscientific observers, and is of very little value. It is a fact of common observation with dentists that individuals know very little accurately of what is going on in their own mouth, and consequently often make positive but inaccurate statements with regard to their teeth. The statements of parents, also, with regard to the condition of their children's teeth, are very unreliable; they fail to distinguish temporary from permanent teeth, supernumerary from normal teeth, and a normal from an abnormal number. The teeth are sometimes so irregular that a double row exists at some parts of the arch, and the phenomenon is explained as due to a third set of teeth. The late eruption of certain teeth, notably the wisdom, which may be delayed till middle or advanced life, often gives rise to a reported case of third dentition, a few teeth being represented as a whole set. The matter is so clearly stated by Salter that I cannot do better than quote from the "Dental Pathology" (Wm. Wood & Co., 1875, p. 32), as follows: "There is no recorded instance of the occurrence of a third set of teeth in the writings of any modern observer of scientific repute; but the authorities of earlier date who have asserted the fact are so respectable that it is difficult altogether to discard from one's mind the idea that the circumstance has occurred in some shape." Later authorities than Salter, while in the main holding his view, yet strengthen somewhat the probability of the occurrence of a third dentition by cases which have been under fairly good observation. The conclusion to be drawn is, that a third dentition probably has occurred in rare instances, but that the vast majority of reported cases are spurious, the error having been caused by the presence of supernumerary teeth, irregular and crowded teeth, or by teeth which have been delayed in their eruption till late in life.

While the existence of an extra dentition remains in doubt, the entire absence of one or both of the normal dentitions is an established fact; such cases, however, are decidedly rare, especially those in which neither dentition has occurred. There is usually associated with this condition a failure in the growth of hair throughout the body. The condition of the alveolar ridge in such cases is similar to that which ensues on the extraction of the permanent teeth. Artificial substitutes, however, are not always necessary, inasmuch as the gum, in such cases, is very tough, and capable of performing with remarkable facility the duties of mastication.

Pathology in the Time of Dentition.—The deciduous teeth are sometimes erupted at birth. An interesting statement of cases of this kind is given in the "American System of Dentistry," vol. iii., p. 423: "Pliny the Younger has handed down to us several instances of prenatal dentition, the most conspicuous of which was that of a Roman consul, Marcus Curius, who, on account of being born with a full set of teeth was surnamed Dentatus. Zoroaster, the Persian legislator, is also said to have had a complete set of teeth at birth. Louis XIV. of France, and his Secretary of State, Cardinal Mazarin, were each born with two teeth. Richard III. of England, and Mirabeau, are both said to have had congenital teeth. Haller collected a list of nineteen cases of teeth at birth, and very many more have been recorded by others." When deciduous teeth are delayed in their eruption it is commonly due to rickets. A delay in the eruption of the permanent teeth is also frequently noticed. An important cause for this delay is the prolonged retention of the deciduous teeth, an obstacle being thus present which prevents the permanent teeth from taking their place. Cases are on record of deciduous teeth persisting till middle or old age. It often happens, however, that a permanent tooth is kept from eruption because its place has been taken by another permanent tooth which had an earlier start, and which has occupied all the available room. This is especially liable to happen with the superior canines, on account of their coming to the surface after the lateral and the first bicuspid have taken their place in the arch. If, as often happens, the temporary canine has been prematurely extracted, allowing the adjoining teeth to close in the gap, or if the arch is unusually narrow, or the teeth unusually large—and sometimes the two latter conditions exist together—then the canine is likely to be crowded out beyond the arch or to be imprisoned in the alveolus. The canine may be permanently imprisoned, or until the extraction of a bicuspid or lateral incisor offers it a chance to erupt.

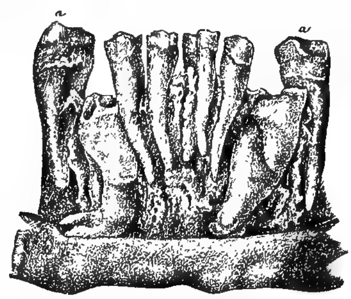

Fig. 3770.—Illustrates the Impaction of both Lower Canines. It occurred in a person of advanced age, and the impacted teeth were not visible above the gum. The canines are kept from eruption by the neighboring bicuspids and lateral incisors. (Wedl.)

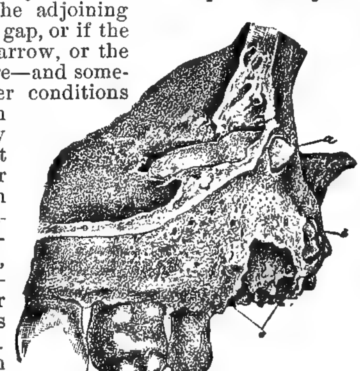

Fig. 3771.—Illustrates the Impaction of a Right Superior Lateral (*a*), which lies in the superior maxillary bone at right angles to its normal position. (Wedl.)

The wisdom teeth are always very liable to detention within the jaw, and their eruption may be either prevented or long delayed. This happens from causes similar to those just described with regard to the canine. The modern civilized jaw seems to be made too short to contain a full complement of developed teeth, and, as the wisdom teeth come last, they, though of stunted size, are frequently unable to enter the arch. Imprisoned or partly erupted wisdom teeth, especially of the lower jaw, may cause very serious symptoms, both local and reflex. The local symptoms consist of pain and swelling in the vicinity of the tooth; the reflex symptoms of neuralgias about the

head, and a tonic contraction of the muscles which close the jaw. In some cases an abscess may be formed which, if lacking prompt exit, may open by fistula on the outside of the face at the angle of the jaw, or in the neck, or even as low down as the subclavicular region. Imprisoned canine and incisor teeth are sometimes found far from their normal position. Cases are cited where the crown of the superior canine has penetrated the nasal cavity and the antrum. Canines have also been located in the palatine portion of the superior maxillary bone. Lower canines have been found with their long axes parallel to the body of the jaw, at or near the tips of the roots of the inferior lateral and bicuspids. The superior lateral may be delayed in its eruption, or imprisoned for want of room in the arch, and may in consequence take abnormal positions similar to those taken by the superior canine.

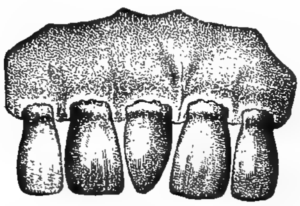

Fig. 3772.—A Conical Supernumerary Tooth located between the Superior Central Incisors. (Carabelli.)

Pathology in the Number of Teeth in a given Dentition. —In connection with both the first and second dentitions we find, at times, both an excess and also a deficiency of teeth. Teeth in excess of the normal are called supernumerary teeth. Such may be coincident in time of eruption with the teeth in whose neighborhood they appear, or they may precede or follow. Supernumerary teeth are divided into two main classes —teeth whose form differs from that of normal teeth (conical teeth), and teeth whose form resembles that of normal teeth. Supernumerary teeth are not common in connection with the first dentition; when they occur they are found more frequently in the lower jaw, and belong in shape to the second class, inasmuch as they resemble the teeth with which they are associated. The duplicate tooth is usually a lower incisor, and it takes its place regularly in the arch, being erupted at about the same time as its companion incisor. Supernumerary teeth are more frequently found in connection with the second dentition, and are usually located in the upper jaw.

They as a rule make their appearance just after the adjoining tooth is erupted. Conical supernumerary teeth are the most common kind. They have the same structure as normal teeth, but in shape resemble a diminutive cuspid. Their crown, however, has not the angular outline belonging to that tooth, but is cone-shaped, as their name implies. The root is round and tapering. These teeth occur most frequently in connection with the superior incisors. One may be located between the two centrals in the arch, or between the central and the lateral. They may be placed without the arch, on either its labial or palatal side. Conical teeth are not commonly found adjoining the molars, bicuspids, or cuspids, though they may exceptionally be found in all these localities. If found outside the arch, conical teeth are of no value, and should be extracted; if found in the arch, it often becomes a question whether their presence or absence produces the greater deformity. Supernumerary teeth which resemble normal teeth are generally found among the upper incisors and regularly placed in the arch; they do not necessarily produce deformity, and by the unprofessional eye would not be noticed. A supernumerary superior lateral is most commonly found; next in frequency comes the superior central, while duplicates of the superior molars, bicuspids, and canines are rare. Carl Wedl, in his "Pathology of the Teeth," gives a drawing of the superior and inferior maxillæ of a negro, in which appear four molars on each side of both the upper and under jaw, beside an extra bicuspid in the lower jaw, making five supernumerary teeth in all; the molars are all in the dental arch, but the bicuspid is situated at the inner side of its neighboring bicuspid. A third kind of supernumerary tooth, sometimes described, is called the cubic-crowned tooth; it resembles in shape the lower bicuspid, and occurs in the anterior part of the mouth behind the superior incisors.

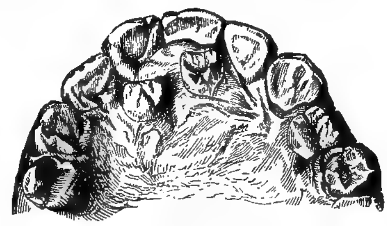

Fig. 3773.—Shows two Cubic-crowned Supernumerary Teeth, occurring behind the Upper Central Incisors. (Salter.)

Pathology in the Arrangement of the Teeth.—A pathological arrangement or irregularity may affect groups of teeth or individual teeth. Among the irregularities which affect groups of teeth are cases in which the anterior teeth of the upper jaw project so far in advance of the corresponding teeth of the under jaw that a considerable space exists between the anterior surface of the lower teeth and the posterior surface of the upper teeth. This arrangement is in many cases hereditary, but may be induced by thumb-sucking in infancy. Infants addicted to this habit place the thumb between the front teeth and pry the upper teeth forward, using the under as a fulcrum. The force exerted is very slight, but, being continued for perhaps several hours during the day, is sufficient to move the imperfectly calcified bony alveolus.

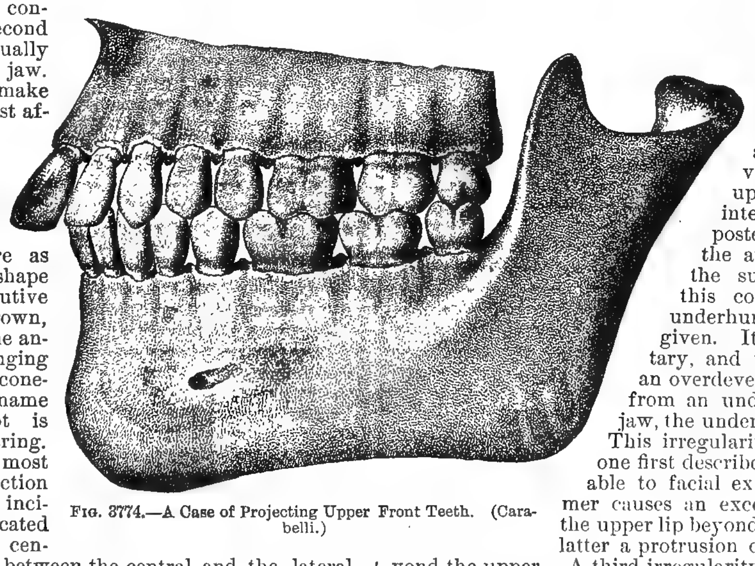

Fig. 3774.—A Case of Projecting Upper Front Teeth. (Carabelli.)

An irregularity the reverse of the above, and of frequent occurrence, is produced when the anterior teeth of the under jaw are placed in advance of those of the upper jaw, leaving an interval between their posterior surfaces and the anterior surfaces of the superior teeth. To this condition the name underhung jaw has been given. It is usually hereditary, and results either from an overdeveloped under jaw or from an underdeveloped upper jaw, the under jaw being normal. This irregularity, as well as the one first described, is very unfavorable to facial expression. The former causes an excessive protrusion of the upper lip beyond the under, and the latter a protrusion of the under lip beyond the upper. A third irregularity is produced when the superior anterior teeth, instead of slightly overlapping the inferior anterior teeth, meet them edge to edge. This arrangement causes no marked facial blemish, but is detrimental to the teeth, which become worn away by edge to edge contact, and thereby shortened.

The six anterior teeth of both jaws are sometimes tilted forward to a marked degree. This irregularity is commonly caused by the loss of molar and bicuspid teeth, which allows the whole force of occlusion to come upon

the anterior teeth. This irregularity causes the upper and under lips to protrude.

On the other hand, the six anterior teeth of both jaws may be inverted, and a corresponding falling in of the lips occur.

A V-shaped jaw is often seen; this irregularity is confined to the upper jaw, whose alveolar arch, instead of being in the form of a parabola, becomes so contracted in front that it resembles in shape the letter V. In such a jaw the room for the tongue is much diminished, and a thick and somewhat indistinct articulation may result.

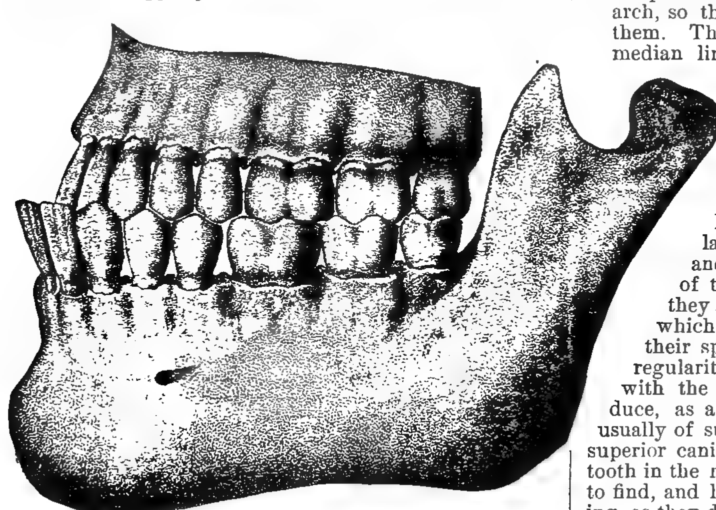

FIG. 3775.—An Underhung Jaw, the Lower Front Teeth in advance of the corresponding Upper Ones. (Carabelli.)

There are cases in which the back teeth are of undue length and prop the mouth open so wide that the anterior teeth do not meet. Such an arrangement is likely to keep the lips from closing, except as the result of conscious effort.

The dental arch may be asymmetrical. Such a condition may be congenital, or produced by tongue-sucking in infancy. In this habit the tongue is crowded against the alveolus bordering the upper molars and bicuspids, a constant repetition of force in this direction unevenly spreading and thus distorting the dental arch.

The "flat mouth," so called, is produced when the six anterior teeth of both jaws are arranged in nearly a straight line instead of in a curve. When so placed they join the bicuspids at a right angle, or nearly so, and give a characteristic flatness to the expression about the mouth.

These various irregularities are, as a rule, confined to the permanent set. An underhung jaw has, however, been noticed in the temporary set, followed by the same in the permanent.

Irregularities of individual teeth are to be explained by several causes, of which the most important is the occurrence of a small-sized jaw associated with large-sized teeth, a small-sized jaw being inherited from one parent and large teeth from the other.

The premature extraction of the temporary teeth is responsible for many cases of irregularity. The place of each temporary tooth is taken normally by a tooth of the permanent set, and, unless the temporary tooth remains *in situ* till the permanent is ready to be erupted, there is danger that the place which the permanent tooth should occupy will be encroached upon by an adjoining tooth.

The too long retention of the temporary teeth may produce irregularity. In this case the temporary teeth become an obstacle to the descending permanent teeth, and may deflect them from their course, forcing them to appear inside or outside the dental arch; or, as not infrequently happens, keeping them imprisoned within the maxillary bones.

Irregularities of individual teeth of the temporary set are rare. There may be a slight twisting or lapping of the incisors, but no great deformity has been observed. Most important irregularities occur in the permanent set; the superior central incisors may stand inside the dental arch, so that the inferior centrals close in front of them. Their crowns may be rotated either toward the median line or away from it, or may overlap each other. In the lower jaw the central incisors, owing to the frequent crowding of the lower anterior teeth, are often twisted or overlapped. The superior laterals are more frequently irregular than are the centrals. The most common irregularity consists in the crown of the lateral overlapping that of the central. The laterals may be placed within the dental arch and held in that position by the interlocking of the lower teeth. Sometimes it happens that they are prevented from eruption by the canines, which have, by premature eruption, occupied their space. The inferior laterals are liable to irregularities similar to those described in connection with the inferior centrals; such irregularities produce, as a rule, no marked deformity, and are not usually of sufficient importance to be regulated. The superior canines are more often irregular than any other tooth in the mouth. The reason for this is not difficult to find, and has already been partly explained. Erupting, as they do, subsequent to the lateral and first bicuspid, it often happens that the space necessary for their regular appearance in the dental arch has been encroached upon by the adjoining teeth. In consequence the canines must either take a position on the outside of the arch or within. Sometimes the canine takes a position alongside the central incisor; when this is the case, the displaced lateral is usually within the arch. A rotated canine is not uncommon; the rotation being toward the median line or away from it. The lower canines are seldom irregular. The upper first bicuspid also usually finds its normal place, on account of the period of its eruption and the fact that its crown is smaller than that of the first temporary molar which it supplants.

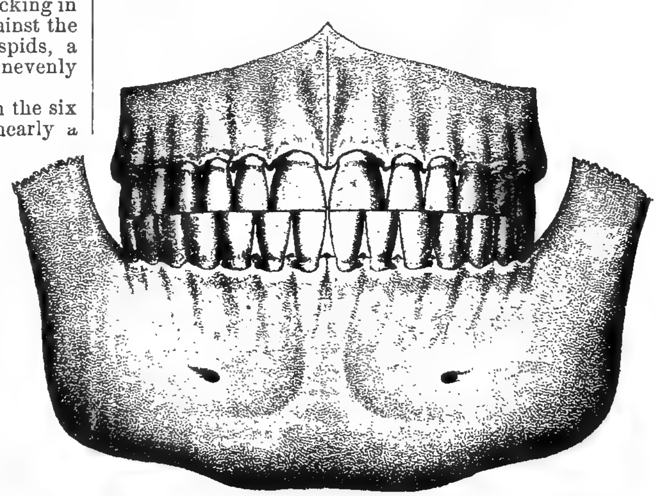

FIG. 3776.—A Case in which the Front Teeth meet Edge to Edge. (Carabelli.)

The second upper bicuspid is much more frequently out of place than is the first. Though its crown takes up much less room than that of the second deciduous molar, which it replaces, still the teeth adjoining it, namely, the first bicuspid and first molar, being in position some time before the second bicuspid is ready to erupt, may encroach upon the space which should have been reserved for that tooth. Such a condition

usually results from the too early extraction of the second deciduous molar. As a result of such extraction the neighboring teeth move together, and sufficient

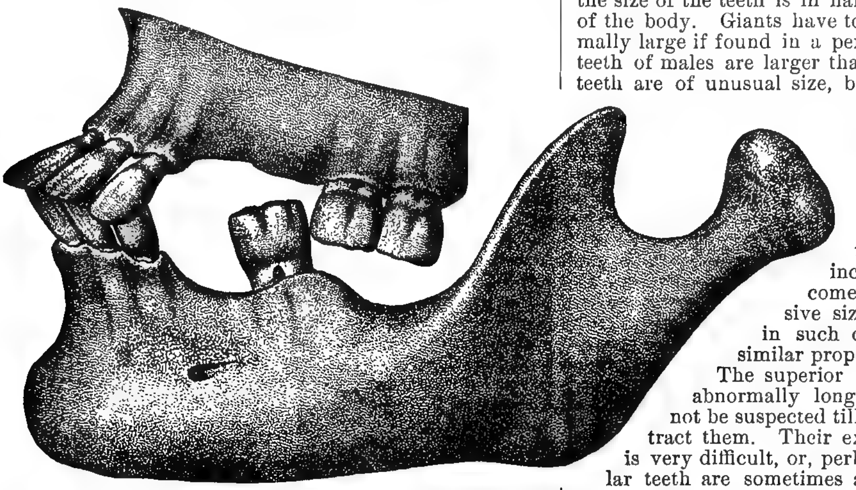

FIG. 3777.—Protrusion of the Anterior Teeth, caused by loss of Bicuspids and Molars. (Carabelli.)

room is not left for the free eruption of the second bicuspid, and that tooth, in consequence, finding its way in the direction of least resistance, is compelled to appear within or without the dental arch, as the case may be. The lower bicuspids are subject to irregularities similar

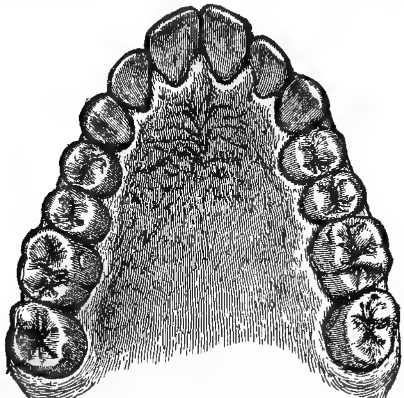

FIG. 3778.—A V-shaped Upper Jaw, from Kingsley's "Oral Deformities." (By permission.)

to those of the upper bicuspids, although they occur less frequently. The first and second molars are rarely irregular in either jaw; each in turn being developed behind teeth already in place, there is nothing to crowd them from their normal position. The third molar, on the contrary, has scanty room for eruption, and in consequence presents frequent irregularity. The lower third molar is often found with its crown presenting toward the posterior surface of the crown of the second molar. Sometimes it is tipped forward so far that the force of occlusion and mastication is borne upon its distal surface. This is the most usual form of irregularity, but the tooth may assume almost any position, even with the crown pointing backward toward the ramus of the jaw. The most frequent

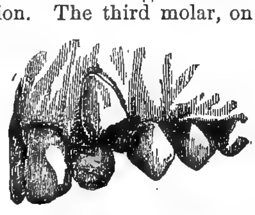

FIG. 3779.—Is a case in which the superior canine has not room to erupt regularly in the arch, and is forced to appear outside of the arch. (Salter.)

irregularity of the upper wisdom tooth is the turning of its crown outward or backward.

Pathology in Size and Shape of the Teeth.—As a rule, the size of the teeth is in harmony with the proportions of the body. Giants have teeth which would be abnormally large if found in a person of ordinary size. The teeth of males are larger than those of females. When teeth are of unusual size, but proportioned to the size of the individual, they are normal for that individual. There occur cases, however, in which certain teeth are entirely out of proportion to the alveolar arch. Such teeth may be too large or too small. Upper central incisors, in rare instances, become a monstrosity in the excessive size of their crowns; the roots in such cases are not developed in similar proportion.

The superior canines sometimes possess abnormally long roots, whose length may not be suspected till an attempt is made to extract them. Their extraction, on this account, is very difficult, or, perhaps, impossible. The molar teeth are sometimes abnormally developed, the crowns and roots alike being of unusual size. An abnormal diminution in the size of the teeth is not commonly found, except in the case of the upper wisdom

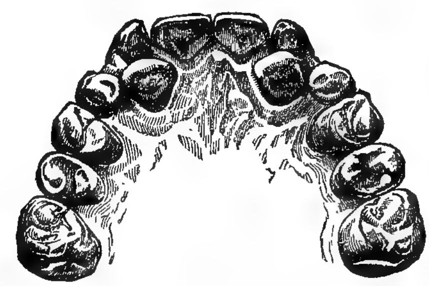

FIG. 3780.—A case in which the superior canines have not room to erupt regularly in the arch, and are forced to appear within the arch. (Salter.)

teeth, which are often quite small, no larger than a conical supernumerary tooth. Teeth which are pathological in shape are frequently observed. Their unusual shape may be due to a constitutional disturbance, occurring during their formative period, or it may be due to a freak of nature—a cause unknown. Of the irregular shapes produced by a constitutional disturbance is to be noticed a pitting of the enamel of the six anterior teeth, and sometimes of the molars in either jaw. The pits may penetrate the entire surface of the enamel, or only a part of it. They may be irregularly disposed, or, as usually occurs, may be arranged in horizontal rows, of which there may be two or three in a single crown. Sometimes the pits are stained a yellowish or yellowish-brown color. This irregular development is caused by some severe infantile disease occurring during the period in which the enamel

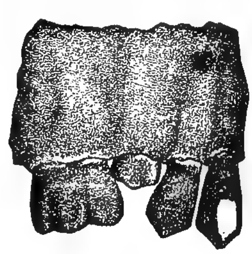

FIG. 3781.—The Right Upper Canine, First and Second Bicuspids, and First Molar. The first molar and first bicuspid have moved together, probably on account of the premature extraction of the second temporary molar. The second bicuspid is thus prevented from erupting regularly, and must force its way outside the arch. In some cases further eruption would cease, and the tooth would remain in the position represented. (Carabelli.)

FIG. 3782.—Represents a superior canine with an unusually long root. (Carabelli.)

of these teeth is being calcified, the process of calcification being thus interrupted. The administration of mercury in the early years of childhood has also been con-

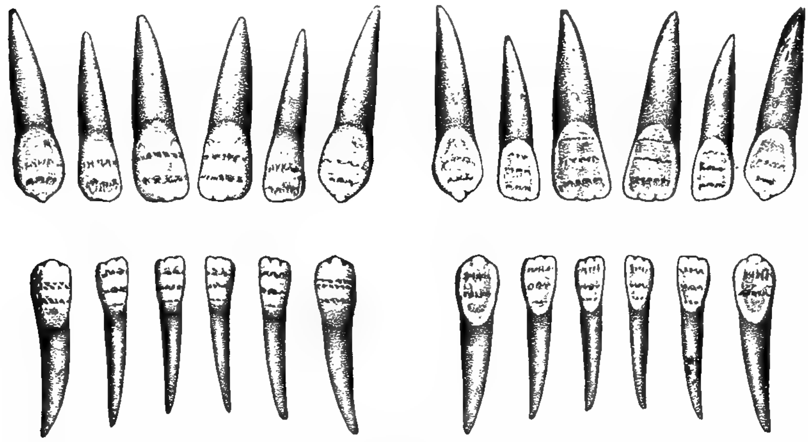

Fig. 3783.—A Pitting of the Enamel of the Six Anterior Teeth, due to infantile disease arresting the process of calcification of the enamel. (Carabelli.)

sidered by some to account for this irregularly formed enamel, but such a view is not now generally accepted.

Another malformation due to a constitutional disturbance is that produced by inherited syphilis. The effects of this disease upon the teeth are most notably seen in the upper central incisors of the permanent set. The crowns of these teeth are stunted in size, are somewhat irregularly placed, and their cutting edges are narrower in width than are the necks of the teeth. The enamel on their cutting edges is imperfectly developed and soon crumbles away, leaving crescentic notches. The upper laterals and canines, as well as the lower centrals, laterals, and canines may be affected in a similar but less marked way. The first molars are usually imperfectly developed, and from a loss of enamel the corners of the teeth are rounded off, giving to the crowns a domelike appearance. As the characteristics of teeth affected by inherited syphilis were first described by Jonathan Hutchinson, it is common to call such teeth Hutchinsonian teeth. They are also called notched teeth, from the notch which may be found in the cutting edge of the six anterior teeth. This notch, however, is obliterated by wear, and thus in time becomes lost as a diagnostic sign. The term peg teeth in this connection is commonly used, and refers to the peglike appearance of the crowns of the anterior teeth. The peg shape does not become obliterated by wear, and always remains a diagnostic sign.

Fig. 3784.—Represents a case of pitting of the enamel, due to arrested calcification. (Carabelli.)

Fig. 3785.

Fig. 3786.

Figs. 3785 and 3786 illustrate the effects of hereditary syphilis on the superior incisors of a boy and a girl, aged twelve and fourteen years, respectively. These cases came under the observation of Henry W. Williams, M.D., and are copied by permission, from his "Diagnosis and Treatment of the Diseases of the Eye."

While inherited syphilis does not always leave its mark upon the teeth, yet when the appearances described are present they are considered to be positive evidence of this disease. The temporary teeth are said, by good authority, to be sometimes affected by hereditary syphilis, and to become notched and peg-shaped after the manner of the permanent teeth.

Pathological shapes to be ascribed to a freak of nature are not commonly met with; still, a large number of such cases have been reported, and drawings made to illustrate them. As one of the more frequent irregularities may be mentioned the fusion of adjacent teeth. There are two kinds of fusion; in one the union is accomplished by the cement of one root becoming increased and uniting itself to the cement of another root. In such cases each tooth has a separate pulp-cavity and independent nourishment, the union being merely upon the outside and not affecting the individuality of either tooth. The other kind of fusion consists in the union of the dentine as well as the cement, and a fusion of the pulp-cavities into a single irregularly shaped space. Such teeth have a common and interdependent life.

Fig. 3787.—A Case of Fusion of the Superior Central and Lateral Incisors.

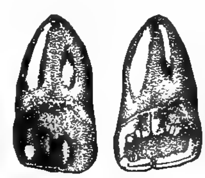

Fig. 3788.—Complete Fusion of the Superior Central and Lateral Incisors. Anterior and posterior view.

Fusion of this kind may be confined to the roots or include the crown as well, in which case a union occurs between the enamel of the two teeth. Fused teeth may be found in the temporary or in the permanent set, and any teeth may be so affected. Generally the fusion is confined to two teeth. It is sometimes unsuspected when involving only the roots, and the attempt to extract either of the fused teeth may result in its companion also being dislodged, or in a failure to extract either. The first form of fusion probably takes place after the formation of the teeth, the latter while the teeth are in a developmental stage.

There are irregular shapes not due to fusion, and which come under the head of miscellaneous forms. The incisors sometimes have their crown developed at right or obtuse angles with their roots, or have more than one root. The canines may have a twisted root, or one with a sharp bend occurring at the middle or upper end of its length. The bicuspids may have two or even three roots. In consequence of the tendency of the roots of the bicuspids to bifurcate, this occasional development of two distinct roots is to be expected. The upper and lower molars may have as many as five roots, or all their roots may be fused into one.

Fig. 3789.—A Right Superior Central Incisor whose root is developed at right angles to the crown.

Pathology of the Component Tissues of the Teeth.—Of these tissues the pulp is most subject to pathological changes. Normally this delicate and sensitive organ is well guarded by rigid walls, which not only protect it against external force, but also against the extreme thermal changes to which the oral cavity is exposed. So long, then, as the pulp remains thus protected, it is not subject to pathological changes; morbid processes do not originate in its tissue. It is true that there are writers who describe affections of the pulp independent of outside influences, but the genuineness of such cases has not been well established. In general the pulp is subject to pathological

Fig. 3790.—A Left Superior Central Incisor having a supplementary root.

changes similar to those found in the soft tissue in other parts of the body; such peculiarities as are found are due to the existence of the pulp within a bony encasement. It must be borne in mind that the pulp is very vascular and very sentient; that the vessels and nerves are supported by a parenchyma of connective tissues, and that the whole organ is contained in an unyielding cavity whose only entrance and exit is a small foramen, whose calibre may not be larger than a bristle. Through this foramen the blood enters, and is in due time returned—a delicate piece of machinery capable of easily performing its duties when in natural adjustment, but impaired or destroyed when affected by force from without. Any agency which interferes with the protection which nature has thrown around the pulp is calculated to set up morbid changes in its structure and interfere with its function. The most potent and frequent agency to be named is caries. When once this disease has located itself upon a tooth it usually progresses, unless checked by appropriate mechanical means, till a considerable portion of the enamel and dentine are destroyed and the pulp laid bare. Long, however, before the pulp is reached, it has been subjected to conditions unfavorable to its healthy activity, and the chances are that when exposed by caries it is already in a pathological condition.

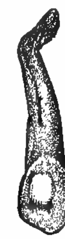

FIG. 3791.—A Right Superior Canine with an abrupt Curve at the end of the Root.

An agency in producing disturbances of the pulp, less important than caries, is the natural wearing away of the substance of the teeth in the process of mastication. Such wear is usually without serious effect upon the pulp up to the period of middle life. Subsequent to that time, however, it may so deprive the pulp of its natural covering as to induce pathological changes.

FIG. 3792.—A Superior Bicuspid with Two very long Roots.

A third outside agency, and one less frequently met with than the other two, is mechanical violence, in the form of a blow or fall, of such a nature as to sever the union between the pulp and its blood- and nerve-supply. Under such circumstances the pulp, as a rule, dies. There are, however, cases reported in which a sound tooth having been pushed out of its socket has been replaced, and the pulp has apparently remained in a healthy condition. Such cases lend support to a supposition that a reunion is possible between the pulp and its blood- and nerve-supply; but this point has not yet been satisfactorily settled.

One of the simplest and commonest pathological affections of the pulp is congestion. A pulp examined in this condition shows increased redness, due to an increased flow of blood to the part and dilatation of the vessels. This condition is brought about through the vaso-motor system, which responds to an irritation of the dentinal fibrils, which are in connection with the nerves of the pulp, and so with the general nervous system. Inasmuch as the normal pulp fills its cavity, an increased supply of blood must compress the tissue in the neighborhood of the vessels. The nerves share this compression, and hence the severe pain which is the usual accompaniment of a congested pulp. Caries of the tooth is the most common cause of congestion of the pulp. Through it a cavity in the direction of the pulp is produced which allows hot and cold drinks, food, and cold air to approach so near the pulp that they irritate it. Salt and sweet substances, also, if allowed to enter the cavity produced by the caries will act upon the dentinal fibrils and irritate the pulp. A congested pulp is hypersensitive, giving pain upon the slightest occasion. A draught of cold water, the effect of which upon a normal pulp might be but a momentary twinge, would cause a congested pulp to ache violently. This ache is one of the more common kinds of toothache; it is violent, intermittent, throbbing. It is very likely to be worse at night when the body is in a recumbent position. Congestion of the pulp does not necessarily result in a permanent pathological condition, provided the environment of the pulp can be so improved as to become normal, or nearly so. The normal environment may be restored by filling the cavity produced by caries, the pulp being thus removed from the near approach of heat or cold and irritating substances. The filling material should be a poor conductor of heat and cold, resembling in this respect, as far as possible, enamel and dentine. Gutta-percha or oxyphosphate cement have proved the best substances with which to protect a congested pulp. It frequently happens that the pulp becomes congested in a tooth which contains a large metallic filling. The metal filling, being a good conductor of heat and cold, conveys injurious shocks deep into the dentine and unfavorably affects the pulp. Such a condition may be remedied by substituting a non-metallic filling for a metallic one.

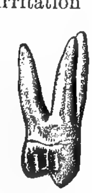

FIG. 3793.—A Superior Bicuspid with Three Roots.

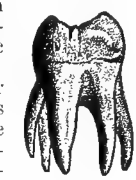

FIG. 3794.—A Molar Tooth with Five Roots.

While a congested pulp may recover its normal condition, it frequently passes into a state of inflammation which may be either acute or chronic. In acute inflammation there succeeds to the active hyperæmia of congestion a stasis of blood in the inflamed portion; the vessels become dilated more than before, and often assume a tortuous course. The leucocytes can be seen leaving the capillaries and invading the surrounding tissue. If the inflammation is purulent, pus cells and broken-down tissues become abundant. The affection may be local, confined to a small point which has been exposed by caries, or it may be general, involving the entire pulp. The organ is swollen, as in congestion, and pain results from pressure upon the nerve-fibres. If the inflammation is very violent, it is likely to destroy the life of the pulp in a short time, through pressure upon the blood-vessels at the foramen. The symptoms attending an inflammation of the pulp are similar to those of a congested pulp, but more severe. The pain is violent, throbbing, paroxysmal, and is commonly known as a "jumping toothache." The tooth is extremely sensitive to heat and cold, to sweet and salt substances, and to pressure within the cavity of decay.

Such an acute inflammation may subside or pass into a chronic inflammation, the symptoms of which resemble those of the acute, but are of a less severe grade. The cause of inflammation of the pulp is caries, which, as a rule, has penetrated to the pulp cavity and laid bare a minute portion of that organ, exposing it to the irritation of foreign bodies, thermal changes, and the secretions of the oral cavity. When suppurative inflammation occurs, the probable agency of bacteria is of interest, as it is well known that many varieties of these organisms exist in the mouth. Their approach to the pulp is made easy through the carious cavity, which lays bare the pulp, and the conditions seem favorable for their peculiar activity. Dr. H. C. Ernst says, in his "Consideration of the Bacteria of Surgical Diseases" (p. 4): "The point being determined that there is at least a very strong probability that no suppuration occurs without the presence of bacteria, the study of the organism concerned in these processes becomes at once of great interest." Dr. Black, in the "American System of Dentistry," while admitting the probability that micro-organisms are influential in suppurative inflammations of the pulp, says that in the cases which he has examined he has as yet failed to discover their presence. The course pursued by an inflammatory affection of the pulp depends largely on the extent to which its surface has been exposed through caries. That there is always such an exposure in case of inflammation of the pulp cannot be affirmed, but that it does exist in the large majority of cases is attested by experience. If this exposure is small and allows no relief to the swollen

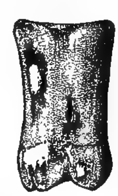

FIG. 3795.—A Molar Tooth whose Roots are fused into one.

condition of the organ, and no sufficient outlet to products of inflammation, then an acute inflammation is likely rapidly to destroy the pulp, and transmit an inflammatory process along the root canals to the peridental membrane. If, however, the pulp has been freely exposed before an inflammation has been started up, then the inflamed pulp has a way of relief to its enlarged substance, and an exit for the products of inflammation. Such cases are more likely to assume a chronic form, inasmuch as the life of the pulp is not immediately threatened. It is a matter of some chance, in the case of a pulp exposed by caries, just how soon an inflammatory affection will be started up, though no pulp when once exposed can long escape. If the cavity which exposes the pulp is hidden away in the back of the mouth, or protected by adjoining teeth, so that the pulp of the tooth is, in a measure, protected from alternations of temperature and severe contact with food, then the inflammatory affection may be delayed, and, when it does come, decay may have so opened the pulp cavity as to greatly modify the severity of the inflammation. On the other hand, when caries attacks the crown of the first molar and lays bare the pulp, it is immediately subject to severe irritation in the process of mastication, and trouble begins at once. Inflammatory affections of the pulp do not tend to recovery, but generally end in death of the pulp. This result may be, however, somewhat delayed by appropriate treatment. The exposed pulp may be capped over with non-irritating, non-conducting material, and thus shielded. It is sometimes possible to prolong the life of the pulp several years, provided the treatment is not long delayed after the beginning of the inflammatory affection. After having been thus treated the pulp may give no further sensation of pain; it does not, however, often regain its normal condition when it has once passed through the inflammatory process.

To alleviate the pain of a congested or inflamed pulp it is important, first, to determine which tooth is giving trouble. The testimony of patients cannot be relied upon to settle this point. They can usually indicate correctly the side upon which the affected tooth is located, but will often point to a perfectly sound tooth as the cause of their pain. A thorough examination should be made, by the aid of the mouth-mirror and a fine exploring point, of all suspected teeth. If a tooth is found with a carious cavity of any considerable size, especially if the cavity is sensitive to the touch of an instrument, it is fair to infer that such a tooth is the one giving pain. The diagnosis can be confirmed by the application of a little cold water to the cavity of decay. Where a congested or inflamed pulp exists, this application will cause an exacerbation of the pain.

Having located the tooth which is the seat of the difficulty, its carious cavity should be washed out with a syringeful of warm water, in order to remove irritating particles of food. The next step is to make an application to the exposed pulp, or, if the pulp is not exposed, to the dentine in the neighborhood of the pulp, which will allay the pain.

A simple and efficacious remedy is the oil of cloves. More powerful remedies are: Carbolic acid, ninety-five per cent.; creasote; a mixture of equal parts of oil of cloves and chloroform; a mixture of equal parts of oil of cloves and creasote.

One drop of any of these remedies is usually sufficient for a single application. The medicine should be applied to the cavity on a pledget of cotton. Care should be taken not to press the cotton too tightly into the cavity, as it might thus become a mechanical irritant to an exposed pulp. In the use of concentrated carbolic acid, care should be taken to prevent its spreading to the adjoining gum and mucous membrane of the lips and cheek.

It is very important, in treating toothache, to know whether the pulp in the affected tooth is alive or dead. If alive, it will respond to thermal changes and be sensitive to exploration in the carious cavity, and should be treated as just described. If the pulp is dead the tooth is usually sore to percussion, and unaffected by applications of cold, though heat will usually be painful.

It is not sensitive to the exploration of an instrument in the cavity of decay. The carious cavity of such a tooth should not be plugged with any dressing, but should be opened freely to give vent to the decomposing pulp in the manner described in the section on affections of the peridental membrane.

Closely allied to inflammation of the pulp is abscess of the pulp. This affection, clinically, cannot always be distinguished from the preceding. Upon microscopic examination, however, it is possible to make out true abscess cavities. These may be deeply situated in the body of the pulp, or near its surface.

The microscopical examination of a diseased pulp is conducted in the following manner: An aching tooth, which is presumably in a pathological condition, is extracted and at once dropped into Müller's fluid; here it is to remain for several weeks till the pulp has become somewhat hard. Then the tooth, after having been wrapped in a cloth, is to be put between the jaws of a vise, and carefully cracked open, and the pulp removed from its cavity. The pulp is again subjected to Müller's fluid, and then to gum arabic, which permeates its sub-

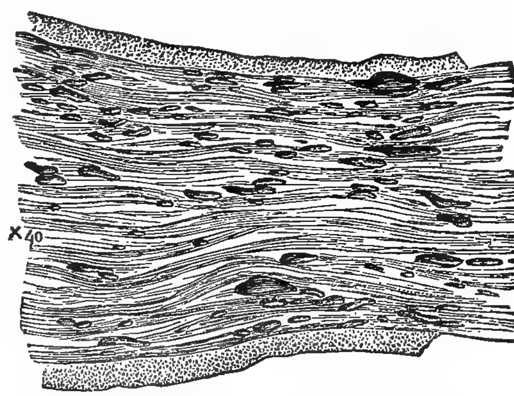

FIG. 3796.—Initial Points of Calcification occurring in the Pulp.

stance and forms a stiff coating outside. The whole mass is then mounted in paraffine, and is in condition to be cut with a microtome. In this way the relation between clinical symptoms of the pulp and pathological changes in that organ can be accurately traced.

Among the more advanced pathological changes in the pulp may be mentioned gangrene. This, as in other parts of the body, may be moist or dry. Gangrene follows upon the sudden cutting off of the circulation from the pulp, as a result of acute inflammations, or violence to the tooth of such a kind as to sever the artery at the apical foramen. A gangrenous pulp is of a grayish-green color, of slight consistency, and fetid odor. In such a pulp the normal structural elements become undistinguishable. In dry gangrene the pulp contracts to a very small compass, and the part of the pulp cavity thus left vacant is occupied by a gas of decomposition. Gangrenous pulps, unless the pulp cavity is freely opened, produce severe inflammation of the peridental membrane.

Another group of pathological changes embraces the various forms of calcification to which the pulp is subject. Among such may be mentioned the nodular form. In this variety small nodules of calcareous matter are sprinkled through the substance of the pulp, giving to it a gritty feel. The calcareous matter is similar in chemical composition to dentine, but does not have its characteristic structure. The calcareous nodules are located between the component parts of the pulp, and are not formed at their expense. This condition seems to be compatible with a healthy activity of the pulp, and apparently does not lead to serious consequences. Its etiology has not been explained. Another form of calcification exists, in which the new-formation takes the place of the normal tissue of the pulp and is formed at its expense. The calcareous points are found scattered here

and there through the pulp, usually in the coronal portion. These points become confluent till an aggregation is formed ranging in size from a grain of sand up to a mass sufficient to fill the entire pulp cavity, coronal and radical portion as well. This form of calcification apparently does not take place when the tooth is in a normal condition, but seems to be induced either by the wearing down of the crowns of the teeth or by caries. In both cases the dentinal fibrils are subject to irritation, and this irritation determines the deposition of lime salts in the substance of the pulp. When once such a deposition begins, it tends to increase till the pulp is changed from a highly sensitive living organism to one practically lifeless, without nerves or vessels, and without the system of tubules which exists in the dentine. During the course of calcification quite severe pain may arise, evidently due to the pressure of the calcareous masses upon the nerve-filaments.

A pathological change similar to that occurring in calcification of the pulp is that which takes place in the formation of secondary dentine. This formation is found on the periphery of the pulp at a place adjacent to a carious cavity, and is deposited by the odontoblastic layer of the pulp, which is the formative agent in normal dentine. Secondary dentine is evidently a means taken by

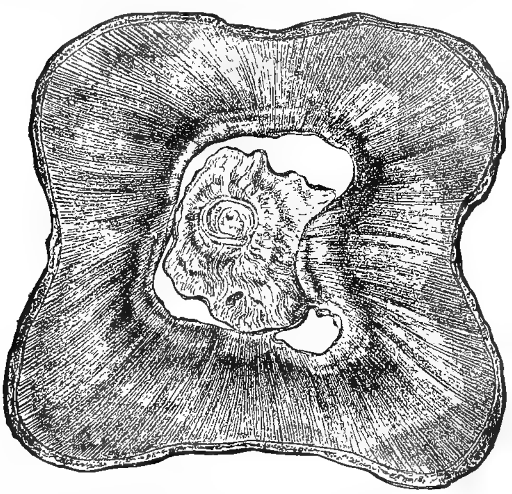

FIG. 3797.—A Section across the Neck of a Molar, showing a Growth of Secondary Dentine in the Pulp-cavity.

nature for the protection of the pulp against the injurious influences incident to advancing caries. Secondary dentine is similar in structure to normal dentine, containing, like it, tubules and fibrils. Its formation is, however, somewhat less regular, and in case the secondary dentine extends far toward the interior of the pulp, it loses its supply of dentinal tubes and becomes less like dentine, and more like a calcified pulp. While the formation of secondary dentine in the neighborhood of decay undoubtedly tends for a time to prolong the life of the pulp, experience seems to show that secondary dentine, when once deposited, tends to increase to such proportions as in the end to destroy the life of the pulp.

The process just described is to be distinguished from that deposition of dentine which takes place by degrees during the whole life of the tooth. This deposit is very slow in formation, and takes place uniformly around the inner side of the whole pulp-cavity. By this physiological deposition of dentine the pulp-cavities in the teeth of old people are reduced to very small proportions. This seems to indicate that the pulp is useful and necessary inversely to the age of the tooth.

There remains to be mentioned a pathological change which increases the size of the pulp. Such an increase can occur only in case the pulp has been exposed. Let such a pulp be subjected to the irritation of foreign substances, and likewise to that of the sharp edges of a carious cavity, and it will sometimes proliferate and fill the cavity.

Why the pulp does not become inflamed and destroyed under such circumstances cannot be explained. This process has usually been noticed in the case of young teeth. The growth may assume the size of a pea, or be larger. It is of fleshy consistency, and is organically united to the pulp by a narrow pedicle, hence it is called polypus of the pulp. In microscopic examination it is found to consist of numerous round and spindle-shaped cells, interspersed with fibrous tissue, and an epithelial covering has been described by some writers. Its blood-vessels pursue a tortuous and irregular course, unlike those in the pulp. No nerves have been found in this tumor, yet it is slightly sensitive to touch, resembling the gum in this respect. Sometimes a mucopurulent discharge issues from its periphery. A polypus protects the pulp against external violence. It is extremely tenacious of life, and will grow again if cut off.

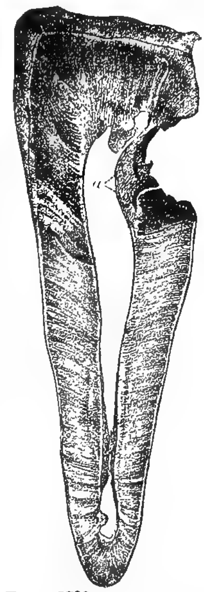

FIG. 3798.—An Incisor Tooth affected with Caries. *a*, A deposition of secondary dentine about the cavity of decay.

A growth similar to a polypus takes place in some cases of fractured teeth. The pulp having been exposed, proliferates through the openings caused by the fracture and forms a tumor outside the pulp-cavity. This tumor, morphologically, resembles a true polypus of the pulp; it has, however, a nerve-supply, and is quite sensitive to the touch, thus differing from a polypus. Salter has named this growth a "sensitive sprouting of the pulp."

Under pathology of the dentine the most important process to consider is caries. This process affects the enamel and cementum as well as the dentine, but has more to do with the dentine than with the other tissues. In the first place, it may be said that caries of the teeth does not resemble caries of bone. The term caries as applied to the teeth is a misnomer, given at a time when the true nature of the process was not understood. However, the term has become so generally used that it cannot now be easily dropped. The pathological change which occurs in caries is a decalcification and disintegration of the several tissues of the teeth. The latter condition follows very quickly upon the former, on account of the large proportion of earthy constituents existing in the parts attacked. Caries may affect any of the teeth of either dentition, but it affects certain teeth more frequently than others. Magitot has tabulated ten thousand cases of caries occurring in the permanent teeth, and his tables show that the tooth most liable to caries is the first lower molar, after which follow in succession the first upper molar, the second lower molar, first upper bicuspid, second upper bicuspid, upper lateral, second upper molar, upper central, second lower bicuspid, upper canine, first lower bicuspid, upper wisdom, lower wisdom, lower canine, lower central and lateral. Caries not only shows a preference for certain teeth rather than for others, but it also shows a preference for certain parts of individual teeth rather than for other parts. Those surfaces of the teeth which are smooth and kept clean by the motions of the tongue, lips, and cheeks, are not attacked by caries; while surfaces presenting an uneven contour, abounding in pits and fissures, are its favorite seat. Hence, we find it located in the crowns of the molars and bicuspids, in the pits on the lingual surfaces

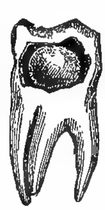

FIG. 3799.—Polypus of the Pulp occupying the Cavity produced by Caries.

of the six superior front teeth, and on all approximal surfaces which, though not uneven, are not cleansed by the motions of the mouth. The buccal and labial surfaces of the teeth, just at the margin of the gum, are likewise often the seat of caries. Caries manifests its presence by a change of color in the tissues attacked. This change may be merely from translucency to opacity, or to a variety of colors ranging from yellow to brown, and even black; sometimes a gray or bluish-gray is seen. As a rule, the slower the progress of the disease the deeper the color of the affected parts, and conversely, the more rapid its progress the lighter the color of the affected parts. Caries usually attacks the enamel first, though it may begin with the cementum. It starts in a small pit or fissure, where soon the enamel is found to have lost its peculiarly hard and dense surface. Instead of resisting the most highly tempered steel instruments, as does normal enamel, it crumbles away under slight force. Thus a small opening is made through the enamel to the dentine. This opening may be as large as the head of a pin, or it may be very minute. During this process the enamel has become decalcified and disintegrated. Some authorities say that the centre of the enamel prisms are first affected, and others that the interprismatic substance is first destroyed, in consequence of which the prisms separate and fall to pieces. When once caries has perforated the enamel it no longer confines itself to a narrow area, but spreads out laterally between the enamel and dentine. The degree of lateral extension varies greatly, but seems to be somewhat dependent on the structure of the dentine. If the dentine is well calcified, and with few interglobular spaces, the lateral extension is not so great as when the dentine is imperfectly calcified and abounding in interglobular spaces. The carious process in its lateral extension seems to follow the anastomoses of the dentinal tubules, which are very abundant at the junction of the dentine and enamel. After having affected a certain area on the periphery of the dentine, caries penetrates its substance, following the tubules toward the pulp. Inasmuch as the tubules converge

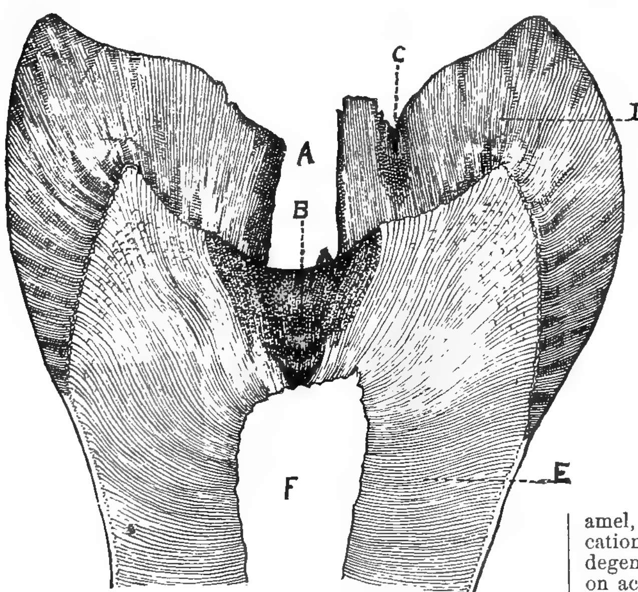

FIG. 3800.—Microscopic Section through a Carious Cavity occurring in a Molar Tooth. A, the initial opening through the enamel; B, the cone-shaped area of decay—the affected tissue being discolored and somewhat softened, but not disintegrated; C, a minute pit in the enamel where caries has just started; D, the enamel; E, the dentine; F, the pulp-cavity.

from the periphery of the dentine toward the pulp-cavity, the progress of caries is marked by a cone-shaped area, the large end of the cone being in the periphery of the dentine, and the small end pointing toward the pulp. Caries tends to penetrate the pulp-cavity, and rarely fails, unless checked by mechanical means. When once the pulp-cavity has been penetrated, the pulp is exposed to the degenerative changes already described, and,

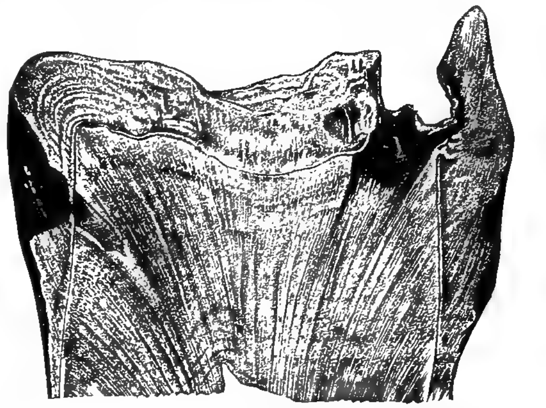

FIG. 3801.—Microscopic Section through a Molar Tooth affected with Caries. The darkly shaded portions represent a brown discoloration.

as a rule, dies and disintegrates. The carious process then invades the pulp-cavity, meanwhile spreading laterally through the dentine from the area originally attacked, and disintegrating the enamel from the under side. By degrees the crown of the tooth becomes so hollowed out by the continuous softening and disintegration of the dentine that the shell of enamel left becomes unable to withstand the force of mastication, and consequently is broken away. Nor does caries stop with the destruction of the crown, it continues its work in the root, enlarging the root-canal at the expense of the surrounding root-substance until the root becomes a mere shell, and is finally entirely disintegrated. The carious process in the root is not so rapid as in the crown, and roots may withstand its action for years.

The microscopic examination of the carious process shows the change in color of the affected parts which has been described, and the disintegration of the enamel rods. The tubules of the dentine appear enlarged in calibre; and their size increases as the process advances. The intertubular substance diminishes with the enlargement of the tubules, and finally disappears with the confluence of adjacent tubules. Micro-organisms are found in great numbers within the tubules.

In the cement, the carious process is similar to that found in the dentine. The lacunæ and canaliculi are enlarged at the expense of the surrounding tissue, which softens and breaks down as the process advances.

Micro-organisms are present as in carious dentine.

A chemical change to be especially noted in connection with all the tissues affected by caries, is the acid reaction which is invariably present.

Etiology of Caries.—There are certain predisposing causes upon which all are agreed; of such may be mentioned a faulty calcification of the enamel, which leaves the dentine exposed; a faulty calcification of the dentine, which leaves it less able to resist degenerative changes; a crowded condition of the teeth, on account of which it is difficult to keep the spaces between the teeth clean.

With regard to the exciting or immediate causes of caries, there has been great diversity of opinion. Of the ancient pathologists, some ascribed caries to a disturbance in the "humors of the body." Others regarded it as due to the ravages of worms which infested the oral cavity.

When we come to observers of scientific repute, we find that the older ones held to a vital or inflammatory theory. According to them, the disease began from

within, by an inflammatory process of the dentine or pulp, the process in dentine resembling caries of bone; hence the term caries was applied to it also.

The vital theory of caries has been effectually disproved by the fact that when natural teeth have been mounted upon artificial plates, and thus worn in the mouth, they have been subject to caries precisely resembling the caries of the teeth normally situated in the jaw.

By others, caries was considered to be a sort of gangrene, due to a disturbance in the nutrition of the dentine.

When, however, the secretions of the mouth came to be studied with reference to their possible agency in producing caries, and when they were found to be at times acid, and when, also, the acid fermentations occurring in the mouth came to be studied in this connection, there was developed what is called the acid theory of caries. According to this theory, caries originates from without and not from within, as those holding the vital theory claimed. The active agency in producing it is acids, which are always present in the mouth, due either to acid secretions or acid fermentations. These acids are to a large extent, it is true, neutralized by the alkalinity of the normal mixed saliva; but in some places, as in the crowns of molars and in the spaces between the teeth, the acid secretions are so protected from the neutralizing influence of the saliva that they are able to retain their reaction and attack the enamel, decomposing the phosphate of lime and other mineral constituents, of which it is largely composed. Having penetrated the enamel, the acids act in a similar manner upon the dentine. According to this theory the tissues of the tooth are affected by chemical decomposition, as if there were no vital element whatever concerned. To substantiate this view many experiments were made, by subjecting extracted teeth to the influence of a weak acid solution imitating conditions found in the mouth. Teeth thus treated underwent a softening and decalcification similar to that found in the mouth in the case of caries. The point was thus well established that caries consisted in the decalcification and disintegration of the mineral constituents of the teeth by an acid.

While some have held a vital theory to account for caries, and others an acid theory, still others again have taken middle ground and held a chemico-vital theory.

The discovery of the presence of micro-organisms in the tubules of dentine affected by caries was an important step in advancing our knowledge of the process. The name of leptothrix buccalis was given to these organisms when first discovered. Though their true agency in caries was not at once understood, they were considered to play an important rôle. During the last few years, however, extensive investigations have been made to determine more accurately the nature of the micro-organisms found in the mouth, and their relation to the process of caries. The most valuable of these investigations have been conducted by Dr. W. D. Miller, of Berlin. His method has been to infect sterilized culture media of various kinds with neutral saliva or with neutral carious dentine, and he has found, invariably, that, when the culture medium contains sugar, an acid is produced. By successive cultures he has isolated the organisms which produce the acid. Of the organisms he writes as follows: "We have, then, in carious dentine, two distinct fungi—one always, the other often, present; the former surely, the latter probably, producing lactic acid from sugar" ("American System of Dentistry," vol. i., p. 803). Perfectly sound dentine, subjected to a pure culture of the fungi just mentioned in a medium containing sugar, underwent, in course of time, typical caries. According to Dr. Miller—and his theory is now quite generally accepted—the history of caries is as follows: It starts wherever, from the contour of individual teeth or from the relation of one tooth to another, a collection of food is possible. In every such collection are multitudes of micro-organisms which are capable of thriving in the presence of sugar, and of decomposing this substance and forming lactic acid. This acid decalcifies the enamel and forms a small pit which, being constantly filled with food, offers a favorable nidus for the continued growth of the same organisms. When the enamel has been penetrated, the organisms begin to multiply in the tubules of the dentine, and there continue the decomposition of sugar absorbed from the mouth. The resulting lactic acid enlarges the tubules by the decomposition of the mineral constituents of the dentine. According to this theory, the secretions of the mouth have very little to do with the production of caries. It is possible that at one time the secretions of the mouth may be more unfavorable to the life of micro-organisms than at another, since it is well known that, at certain times and in certain individuals, caries progresses very rapidly.

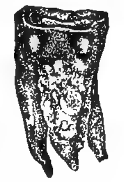

Fig. 3802.—Nodular Hypertrophy of Cement in the case of a Superior Molar Tooth.

A condition resembling caries, and yet essentially differing from it, is erosion. Erosion is commonly found on the labial surface of the six anterior teeth, either at the margin of the gum, or between it and the cutting edge. It also sometimes affects the bicuspids and molars. Erosion produces shallow cavities, which involve the enamel and penetrate to the dentine. These cavities are larger at their external opening than in their deeper parts, and are smooth, hard, and polished throughout. They present neither the characteristic softening nor undermining growth which are found in caries. The cavities do not rapidly enlarge, but may become of such size as to threaten the life of the pulp. Caries is sometimes superadded to erosion, thus modifying the course of the destructive process. The etiology of erosion is obscure; but it is usually assigned, in lieu of a more probable cause, to the effect of acid mucus.

Pathological Changes in the Cement.—The most common pathological change of the cement is an hypertrophy, which is due to an irritation of the peridental membrane. This membrane, lying between the cement of the root and the bony alveolus, is at once the formative membrane of the cement of the tooth and of the adjacent bone of the alveolus. When, however, the cement of the root has been completed, the activity of the peridental membrane, so far as its cement-forming function is concerned, normally ceases. It does not resume this function unless subjected to irritation, in which case it may deposit additional cement upon the root in various ways. The deposit may be diffuse, covering the entire root, though most abundant at the apex. It may be nodular, the nodules being found at any point on the root, and being of various sizes: or it may consist of a club-shaped enlargement at the end of the root.

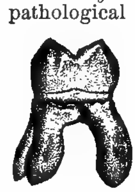

Fig. 3803.—General Hypertrophy of the Cement about the Roots of a Superior Molar Tooth.

The added cement is similar in structure to the primary cement, the union between the two deposits being, as a rule, not noticeable. In certain cases, however, blood-vessels penetrate this secondary deposit of cement, a condition not found in the primary deposit. Hypertrophy of the cement has never been observed in the case of the temporary teeth, and affects the permanent teeth during adult life. The teeth most commonly involved are the upper bicuspids and molars, though the others are not exempt. Hypertrophies of the cement are called hypercementoses, osteomata, and exostoses. Of the causes which produce an irritation of the peridental membrane, and consequent hypertrophy of the cement, perhaps the most frequent is caries with its sequelæ, viz., inflammation and death of the pulp, with extension of the inflammation to the peridental membrane. Another cause is the undue pressure which teeth are sometimes subjected to in the process of occlusion and mastication. This arises when many of the teeth have been lost and the few remaining ones are compelled to bear all the strain of service. In such cases the peridental membrane is over-

Fig. 3804.—Hypertrophy of the Cement about the end of the Root of a Bicuspid Tooth.

worked, literally crowded to the wall, and in consequence may become irritated. The same effect may be produced by the insertion of fillings which project from the crown of a tooth so far as to concentrate the force of occlusion on the filled tooth. While hypertrophy of the cement is commonly due to irritation from undue force, there are cases in which teeth having no antagonists are found to have hypertrophied cement. The symptoms which may arise from an hypertrophy of the cement are caused by the pressure of the new-growth upon the nerves of the peridental membrane and upon the nerves of the pulp at the apical foramen. Many cases of hypertrophy exist which occasion no symptoms, the condition becoming known only after extraction. In old people it is usual to find the cement somewhat thickened, and this change can almost be called physiological, so constantly does it occur. Doubtless the process is so gradual that the surrounding tissues accommodate themselves to the enlarged root, and their nerves are subjected to no irritation. In other cases pain is an important and persistent symptom. The pain may be localized and accompanied by a soreness in the socket, or it may be diffused throughout the jaw or reflected to adjoining parts of the head. Severe neuralgias of the head, face, and neck have been found to owe their origin to the hypertrophy of the cement of a tooth. The tooth may appear to be perfectly sound, in which case it is exceedingly difficult to locate the source of the pain. When, however, neuralgias exist in connection with teeth which, though not carious, are the seat of pain or are sore in the socket, it is fair to suspect either an hypertrophy of the cement or a calcification in the pulp. Not only does an enlarged cement cause severe neuralgic pains about the head and face, but cases of epilepsy and insanity have been reported as due to the same cause. A case from Tomes' "Dental Surgery" is in point. "A lad, a farm-laborer from Windsor, was admitted into the Middlesex Hospital for epilepsy. The usual remedies were tried for six weeks without effect. His mouth was then examined and the molar teeth of the lower jaw found to be much decayed, the fangs of some alone remaining. Although he did not complain of pain in the teeth or in the jaw, the decayed teeth were removed, and the fangs of each were found to be enlarged and bulbous from exostosis. During the eighteen months that succeeded the removal of the diseased teeth, he had not suffered from a single fit, though for many weeks previous to the operation he had had two or three per day."

A second pathological change of the cement is absorption. This is often found in connection with hypertrophy, and occurs at scattered points and produces depressions in the surface of the cement. In cases of long-continued inflammation about the apex of the root, the cement is likely to be in part absorbed, giving a rough outline to the apex.

Pathology of the Peridental Membrane.—Disease of the peridental membrane may be due to a constitutional disturbance, or to pathological affections of the pulp, or may be dependent upon, or associated with, calcareous deposits upon the root of the tooth. Of the constitutional affections which react upon the peridental membrane, Tomes enumerates rheumatism, syphilis, and the exhibition of mercury.

Inflammation of the peridental membrane from rheumatism is independent of caries, and may involve one or more teeth. The inflammation is distributed over the entire membrane, causing a loosening of the tooth and a soreness in the socket. Its course is subacute or chronic, does not tend to abscess, and is amenable to constitutional treatment.

Inflammation of the peridental membrane from syphilis is chronic. Pus may be discharged around the neck of the tooth, which becomes sore in the socket and loose. If the disease is unchecked the teeth may fall out of their own accord, owing to a complete destruction of the peridental membrane. Associated with this process there often occurs a necrosis of the surrounding bone.

Inflammation from the administration of mercury, whether in the treatment of syphilis or not, is associated with ptyalism, and is of a subacute or chronic character. The teeth become loosened and sore in their sockets, and, if the drug is long continued, a discharge of pus around the neck of the teeth and final loss of the teeth may result.

The effect of phosphorus upon the peridental membrane, though not belonging strictly under constitutional affections, is of great interest. Persons subjected to the fumes of phosphorus, as are those who work in match factories, often have necrosis of the maxillary bones. This necrosis starts with an inflammation of the peridental membrane, which is very sensitive to the irritating fumes of phosphorus. As a result of inflammation the membrane is destroyed, and the bony alveolus being thus cut off in large degree from its source of

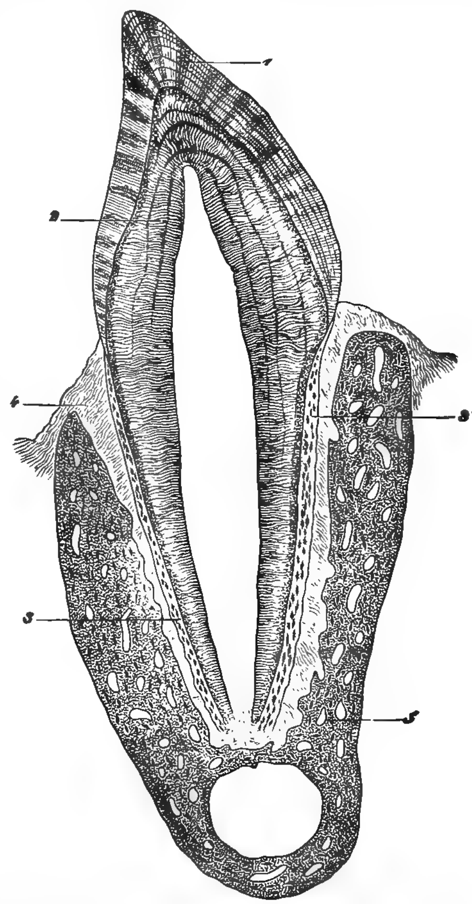

FIG. 3805.—The Relation between the Root of a Tooth, its Peridental Membrane, and its Bony Socket. 1, The enamel; 2, the dentine; 3, the cement; 4, the peridental membrane, which is also the periosteum of the socket; 5, the bony socket.

nourishment, necrosis is invited. It has been found that this disease mainly affects operatives in whose mouth are carious teeth, or who have had teeth extracted while pursuing their occupation. The phosphorus fumes enter a carious cavity and reach the peridental membrane by way of the apical foramen. If, however, the teeth are sound and the gums healthy, phosphorus has little if any destructive effect in the mouth.

Pathological affections of the peridental membrane consequent upon disease of the pulp are of frequent occurrence. When the pulp has become severely inflamed it is common to find, in addition to the symptoms attendant upon simple inflammation of the pulp, a soreness of the tooth in the socket. If the tooth is then percussed with a steel instrument the patient will flinch. This is an indication that the inflammation has proceeded up the root-canal and extended to the peridental membrane situ-

ated around the apex of the root. Symptoms pointing to inflammation around the root do not always appear during the inflammatory stage of the pulp; they more commonly follow its death and putrefaction. When this has occurred, irritating products of decomposition, both gaseous and liquid, pass up through the canal and set up acute inflammation in the membrane at the apex of the root. In the light of our knowledge of the agency of micro-organisms in inflammatory processes, we must consider that the germs, which were active in producing inflammation of the pulp, are also active in the consequent inflammation of the peridental membrane. This membrane being of connective tissue, and richly supplied with blood-vessels, is an excellent field for inflammatory action, and being closely confined between unyielding walls, and having an abundant nerve-supply, is capable of producing symptoms of the severest character. When an inflammatory process has started at the apex of the root, the tissues become swelled and engorged with blood, the condition extending from the apex toward the neck of the tooth. In consequence of the swelling of the membrane, the tooth is pushed slightly from its socket and becomes loose. The clinical symptoms are ushered in by a dull, continuous pain, which is not occasioned by changes of temperature, as is often the case with inflammation of the pulp. The tooth upon pressure feels sore in the socket, yet, during the first stages of the inflammation a grinding of the affected tooth against its antagonists gives some relief. The inflammatory process sometimes stops at this point, but very often goes on to the formation of an alveolar abscess.

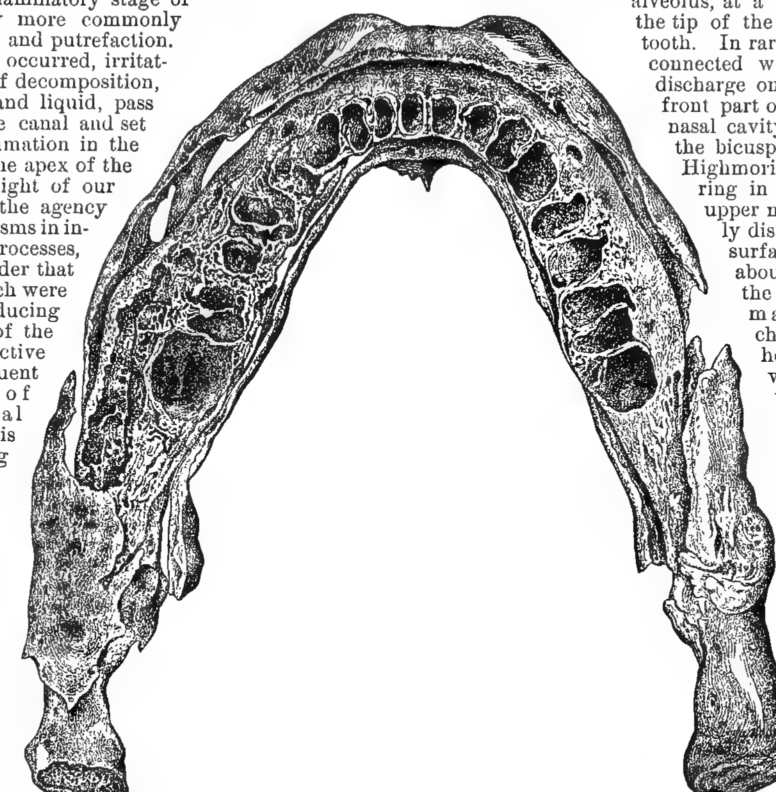

FIG. 3806.—Phosphor-necrosis of the Lower Jaw.

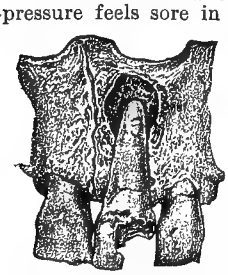

FIG. 3807.—Absorption of Bone, produced by an Alveolar Abscess at the Tip of the Root of a Left Superior Incisor.

Alveolar abscess forms about the tip of the root. As pus collects, the neighboring bony tissue is absorbed, and a cavity is formed varying in size according to the severity of the inflammation. Like abscesses in other parts of the body, it seeks an outlet at the point of least resistance. There are several ways in which the pus may make its escape. It may penetrate the bony alveolus in a line which is, roughly speaking, at a right angle to the root of the affected tooth, and thus make its escape into the mouth, or, in some cases, upon the face. Or it may pass down the length of the root, either between the peridental membrane and the cement, or between the peridental membrane and the bony socket, in both cases discharging about the neck of the tooth. When an alveolar abscess occurs in connection with the six anterior teeth and bicuspids of the upper jaw, it usually discharges on the labial surface of the alveolus, at a point about opposite the tip of the root of the affected tooth. In rare instances an abscess connected with these teeth may discharge on the outside of the front part of the face or into the nasal cavity, and in the case of the bicuspids, into the antrum Highmorii. An abscess occurring in connection with the upper molars most commonly discharges on the buccal surface of the alveolus, about opposite the tips of the roots affected. It may, however, discharge in the neighborhood of the hard palate, when proceeding from the palatal root. Besides these usual points of discharge, the abscess may open into the antrum or upon the outside of the face near the union of the malar and superior maxillary bone. Abscesses formed about the lower anterior teeth usually open on the labial side of the alveolus, within the mouth. They may, however, open on the outside of the face, below the horizontal portion of the jaw. Abscesses in connection with the lower bicuspids usually open on the buccal side of the alveolus, though they may discharge on the face, along the body of the jaw. Abscesses connected with the lower molar teeth usually find exit upon the buccal side of the alveolus, but sometimes on the outside of the face, adjoining the inferior maxillary bone. Cases are reported in which the abscess has opened in the neck, and even as low down as the infraclavicular region. Alveolar abscesses usually assume a chronic condition, and keep up a discharge of pus from their fistulous opening as long as the root in connection with which they have been formed remains in the mouth, or until the pulp-canal of the root has been properly cleaned and filled. The opening of an alveolar abscess upon the face or neck has oftentimes been mistaken for the discharge from necrosed bone. A case coming under the observation of the writer, while in charge of the Dental Infirmary of the Harvard Dental School, will illustrate the point. A farmer, from the western part of Massachusetts, came to the Massachusetts General Hospital to

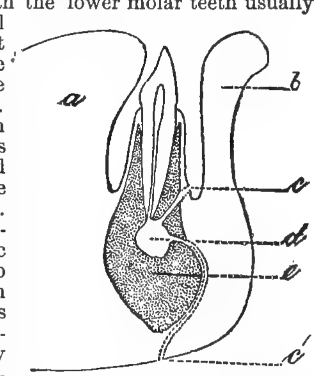

FIG. 3808.—A Vertical Section through a Lower Incisor and surrounding Parts, illustrating two ways in which an Alveolar Abscess may find vent. The first, and more common, way, is by the fistula opening at *c*; the second, and less common, way, is by the fistula opening at *c'*. *a*, the tongue; *b*, the lower lip; *d*, the abscess cavity; *e*, the inferior maxillary bone.

be treated for a fistula opening at the symphysis of the lower jaw. The fistula discharged more or less, and was thought to be due to necrosis of the lower jaw. The condition had existed for about two years, and had been treated by injecting the fistula with various medicaments. At the hospital they declined to operate till his teeth had been examined. Such an examination showed a lower incisor which, though not carious, was believed to contain a dead pulp and to be the origin of the fistula. The tooth was extracted at the Dental Infirmary, and the patient advised to return home and report in a month's time. In due time the patient reported that the fistula had completely healed. While not all cases of fistula about the face are due to dental abscess, yet the teeth should always be examined when such a case presents itself.

The clinical symptoms attendant upon alveolar abscess are well marked and of peculiar severity. Since alveolar abscess starts with simple inflammation of the peridental membrane, the first symptoms are the same as those described under that affection. As the condition advances, however, the pain becomes more intense, the tooth is farther protruded from its socket, and is exquisitely sensitive, the touch of a finger often being sufficient to produce great agony. Sometimes the formation of pus is marked by a chill and rise of temperature. This formative stage may last from twenty-four to forty-eight hours; meanwhile the pus has been working its way through the surrounding bone into the soft parts. When this has occurred the face in the neighborhood of the affected tooth becomes swollen, and there is a marked remission of pain. The mucous membrane of the gum about an alveolar abscess is much congested and swollen, besides being sore to the touch.

As peridental inflammation and alveolar abscess are very common causes of toothache, it is necessary to distinguish between the toothache so caused and that due to irritation of the pulp. Toothache from irritation of the pulp is started by the pressure of food against the pulp, by a sudden variation of temperature, or by sweet or salt substances. The pain is violent, but intermittent, and no soreness of the tooth in the socket, as a rule, exists. Toothache from inflammation of the peridental membrane or alveolar abscess is started by the death and decomposition of the pulp. The pain is continuous; it is increased by the application of heat, diminished by the application of cold. The tooth is sore in the socket, and if the crown is tapped with an instrument the patient will flinch. The tooth is protruded from the socket, the gums are inflamed, and the face swollen.

The treatment of peridental inflammation or alveolar abscess is, first, to remove the cause of the irritation. If the tooth is without value to the individual it should be extracted. This is the quickest way out of the difficulty. If, however, it is desirable to preserve the tooth, its pulp-cavity should be at once opened and cleansed from all decomposing material. If this is done in the first stage of the difficulty it is usually sufficient, and, the source of irritation being removed, the inflammation subsides. If the case be one of alveolar abscess the cleansing of the pulp-cavity is of advantage, not only in removing the source of irritation, but also in giving a vent to the forming abscess through the root-canal. In many cases, however, the abscess will open through the alveolus in spite of treatment. Such an opening can sometimes be hastened by incising with the lance over the affected root. Whether pus can be reached with the lance or not, the incising of the gum gives relief by diminishing the congestion of the part. The use of leeches upon the gum is an old and often effective remedy. The tincture of iodine painted upon the gum is of common use; also the application of capsicum plasters, slippery-elm poultices, and roasted raisins. A poultice should never be applied to the outside of the face, on account of the danger of causing the abscess to discharge externally and leave a scar upon the face which is a permanent disfiguration.

Pathological Affections of the Peridental Membrane dependent upon, or associated with, Calcareous Deposits on the Teeth.—Calcareous deposits are of two classes: those originating from the saliva, and called salivary tartar or salivary calculus, and those originating apparently from a serous exudation from the peridental tissues, and called serumal calculus. The salivary tartar is composed mainly of phosphate and carbonate of calcium, which are contained in the saliva and are precipitated upon the teeth. It is found in greatest abundance on the buccal sides of the upper first molars, near the opening of the parotid gland, and on the lingual side of the lower anterior teeth, near the opening of the submaxillary and sublingual glands. Salivary calculus is first deposited at the neck of a tooth, and, if not removed, spreads both toward the cutting edge and in the opposite direction up the root. In its progress along the root it presses away the gum from the neck of the tooth and separates the peridental membrane from its attachment to the cement. If allowed to rest in contact with the peridental membrane, it destroys its life, and also that of the adjacent bony alveolus, thus largely diminishing the natural support of the tooth. In this way the teeth affected become loosened, and may be entirely dislodged. Salivary calculus, though, as a rule, limited to the regions described, may in much neglected mouths cover the entire lingual side of the lower teeth and the buccal sides of the upper teeth. The treatment of this deposit consists in its removal, after which the peridental membrane quickly resumes its normal character, except such portions as have been destroyed, and the gum closes around the neck of the tooth.

The second form of calcareous deposit, called the serumal, has nothing to do with the saliva, nor is it limited to certain localities in the mouth. It is supposed to be due to a deposition from serum exuded from the gingival margin of the gum and peridental membrane; this deposition taking place in consequence of irritation. It may affect any of the teeth, and is located at the margin of the gum, often hidden from sight. In color it varies from yellow to brown, and even black. It often encircles the root of the tooth, but may be deposited in patches. It increases slowly, but is destructive to the peridental membrane, which becomes separated from the root. The alveolar bony processes about the neck of the tooth are in time absorbed, and the natural support of the tooth is diminished.

In connection with this deposit there may be a flow of pus, due to irritation of the peridental membrane. To this condition the name pyorrhœa alveolaris has been given. While salivary calculus causes the loosening and falling out of the lower front teeth, the serumal deposit may effect the loosening and falling out of any of the teeth, and is the most common cause of that result.

There remains to be described an affection of the peridental membrane which is very destructive to that tissue. It is usually associated with a deposit of serumal calculus, and may be very similar to the affection just described. The calcareous deposits are, however, more likely to be in patches, and to advance more rapidly to the apex of the root. By this means pockets are formed along the side of the root, due to a separation of the peridental membrane from the cement of the root. In the first form of serumal deposit the peridental membrane is separated from the tooth around the entire circumference of the root, and from its neck as far up as the deposit reaches; the tips of the root, meanwhile, being firmly attached to the peridental membrane until the tooth falls out. In the second form, however, the root may be separated from its peridental membrane on one side up to its apex, and in other parts firmly attached. At the apex the root is often entirely separated from its surrounding membrane, though at its neck there may be a fairly good union. Whether the deposit of calculus is due to the inflammation of the peridental membrane, or the inflammation is due to the deposit of calculus, is not decided. This form of calculus is associated with a flow of pus and rapid destruction of the peridental membrane. This membrane having been destroyed, the tooth loses its hold in the socket, and in time drops out. There is some reason to suppose that this disease is due to a special micro-organism, and that it is infectious. On this account it has been called infectious pericementitis.

The term pyorrhœa alveolaris is commonly applied to this as to the preceding condition. The treatment of both kinds of serumal calculus with associated inflammation of the peridental membrane is to remove the deposits of calculus and to keep them removed. To this must be added thorough cleanliness of the teeth, and a washing out of all pockets around the necks of the teeth produced by the separation of the root from its membrane. The use of antiseptic fluids in such pockets is a desirable and effective treatment, especially in that form of deposit last described. In people of middle or advanced life calcareous deposits are more destructive to the teeth than is caries.

The pathological condition commonly described by the term a "dead tooth" is one which needs explanation. When the pulp of a tooth dies the tooth is often called a dead tooth. The term thus applied is incorrect and misleading. When the pulp dies it is true that the main source of nourishment for the tooth has been cut off; but, while the peridental membrane is alive and healthy the tooth still receives nourishment from it. That this membrane can nourish the dentine is evident from a reference to the plates on dental anatomy, where the dentinal tubules are shown to connect with the granular layer of the dentine, and the granular layer to be in connection with the canaliculi of the cement. The cement is nourished by its periosteum, which is the peridental membrane. A pulpless tooth is not necessarily, nor is it usually, a dead tooth. If its peridental membrane is in a healthy condition, and its root-canals thoroughly cleaned and filled, it may be as comfortable and as useful an organ as a tooth having a pulp.

When, however, both the pulp and peridental membrane—the two sources from which a tooth gets its nourishment—have been destroyed, then the tooth is dead, and is a foreign body which nature quickly rejects.

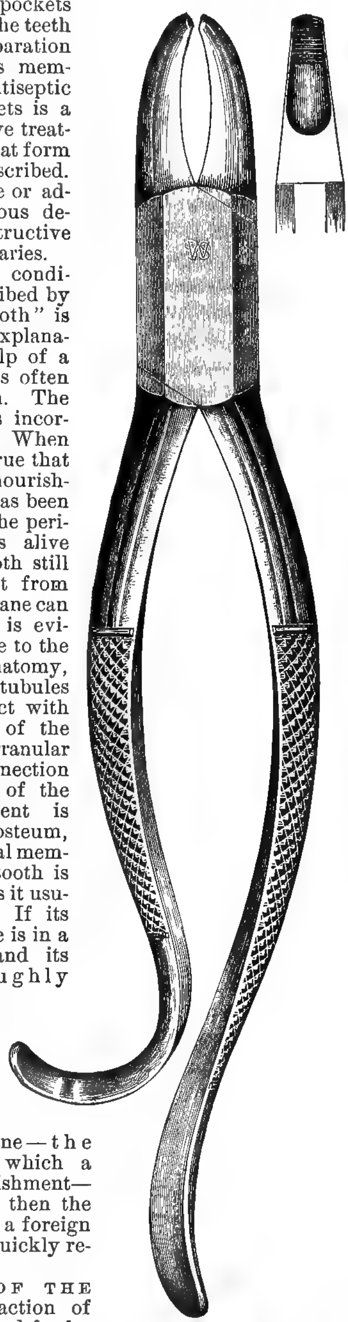

FIG. 3809.*—Forceps No. 13. Incisor, Upper. Also made with straight handles.

EXTRACTION OF THE TEETH.—The extraction of the teeth may be called for by various conditions, of which the more common are:

1. A crowded condition of the teeth which threatens or has caused irregularity. Teeth may be placed entirely outside or inside of the dental arch. The extraction of such teeth is often advisable. It may, however, be laid down as a rule that the superior canines and central incisors should not be extracted to correct irregularity; nor should the inferior canines, except in rare instances. For example, it often happens that when the superior canines make their appearance through the gum there is no room for them between the superior lateral incisors and first bicuspids. As the canines descend they in consequence take a position outside of the arch and are a deformity. They are not on this account, however, to be removed, because by their position and size they give character to the expression of the face. A bicuspid, or sometimes a first molar, should be extracted instead, and thus room gained for the canine. In many such cases, however, there is no need for extraction, inasmuch as the enlargement of the dental arch, either by nature or by mechanical appliances, will furnish the required room.

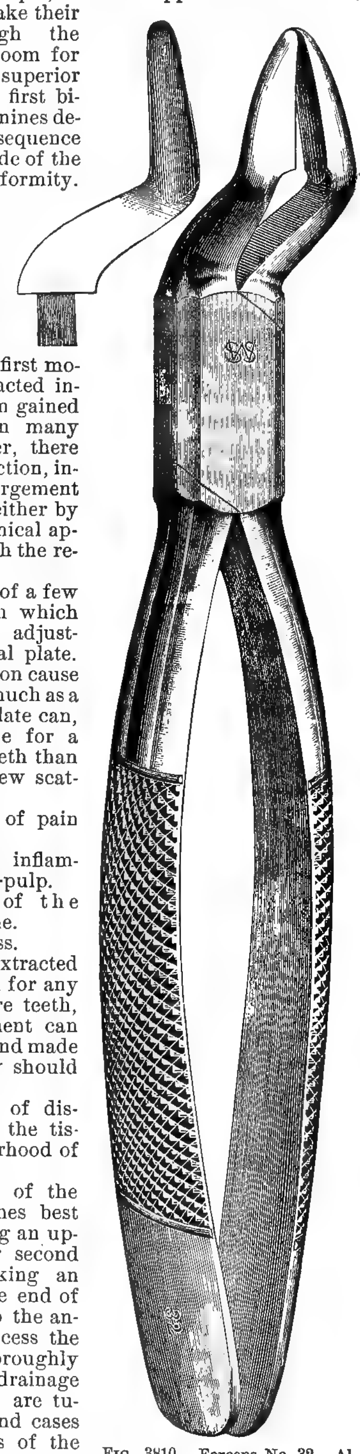

FIG. 3810.—Forceps No. 32. Alveolar, Bayonet Shape.

2. The existence of a few teeth in the mouth which interfere with the adjustment of an artificial plate. This is a very common cause for extraction, inasmuch as a more satisfactory plate can, as a rule, be made for a mouth having no teeth than for one having a few scattered teeth.

3. The existence of pain due to:

a. Congestion or inflammation of the tooth-pulp.

b. Inflammation of the peridental membrane.

c. Alveolar abscess.

More teeth are extracted to relieve pain than for any other cause. Where teeth, however, by treatment can be relieved of pain and made useful organs, they should not be extracted.

4. The existence of diseased conditions of the tissues in the neighborhood of the teeth.

An inflammation of the antrum is sometimes best treated by extracting an upper first molar or second bicuspid and making an opening through the end of the root-socket into the antrum. By this process the antrum can be thoroughly cleansed and good drainage established. There are tumors of the jaw, and cases of caries or necrosis of the maxillary bones, which necessitate a removal of teeth.

5. The persistence of the temporary teeth when the permanent teeth are about to erupt.

It may be laid down as a rule that the temporary teeth

* The forceps are numbered according to the catalogue of the S. S. White Dental Manufacturing Co., published in August, 1887.

should not be removed until the permanent teeth are ready to take their place. When this condition exists the roots of the temporary teeth have been for the most part absorbed, and the crowns have become loose. While the above rule should be adhered to as far as possible, yet there are cases in which severe inflammation connected with the temporary teeth requires their premature extraction.

The process of extraction and the instruments employed vary greatly with the different teeth in the mouth. A knowledge of the number, shape, and size of the roots of the teeth is necessary to insure success in their re-

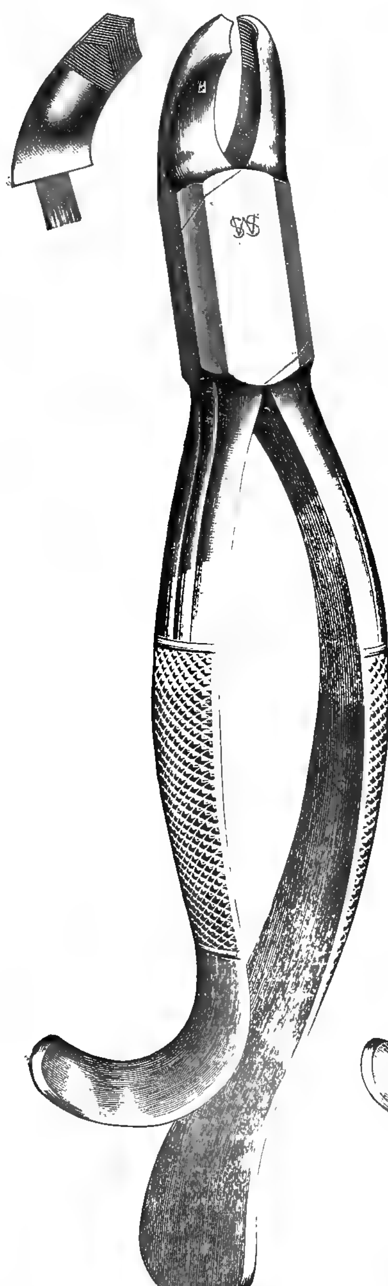

Fig. 3811.—Forceps No. 18. Molar, Upper. Right Side.

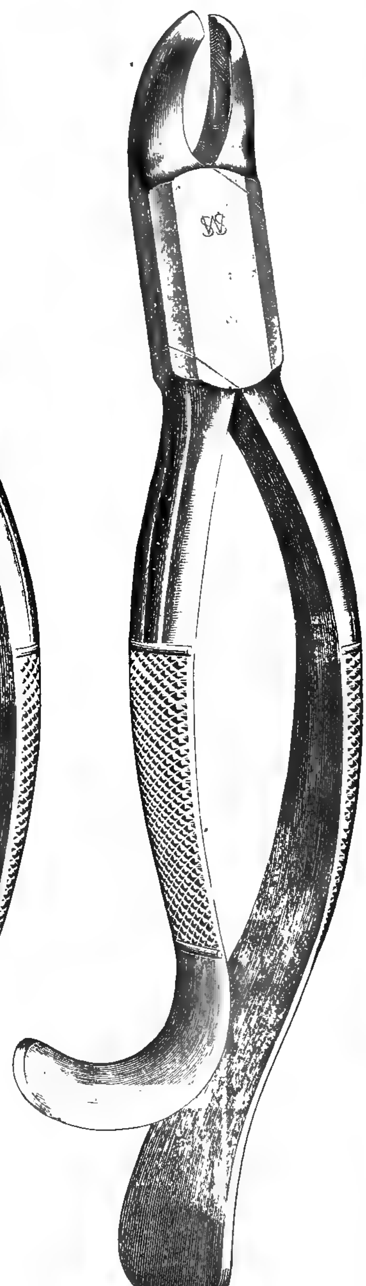

Fig. 3812.—Forceps No. 18. Molar, Upper. Left Side.

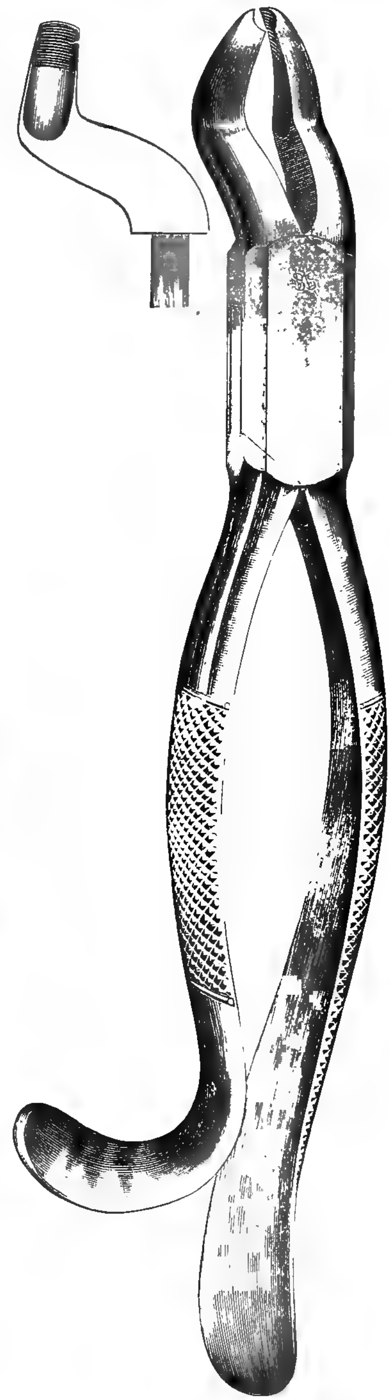

Fig. 3813.—Forceps No. 10. Dentes Sapientiæ, Upper. Either side. Also made with straight handles.

The Process of Extraction.—The process may be divided into three stages:

1. Seizing the tooth with the forceps.
2. Loosening its connection with its surroundings.
3. Removing the tooth from its socket.

moval. To extract the teeth of the upper jaw, the patient should be placed with the head thrown well back, and the operator should stand at the patient's right side. With the left hand the lips and cheeks should be retracted and the upper jaw firmly grasped.

The upper central incisors are extracted with forceps No. 13. Its beaks are made to adapt themselves to the nearly conical neck of this tooth. This forceps should be applied with one beak at the labial surface of the neck of the tooth, and the other at the lingual surface. The beaks of the forceps should be carried well up between the margin of the gum and the root of the tooth. When the tooth has been thus grasped, it should be gently but firmly rotated, in order to loosen it from its socket. A forward-and-back motion may with advantage be combined with the rotatory motion. When the tooth is felt to have been loosened, it should be removed by a steady pull in the direction of its long axis.

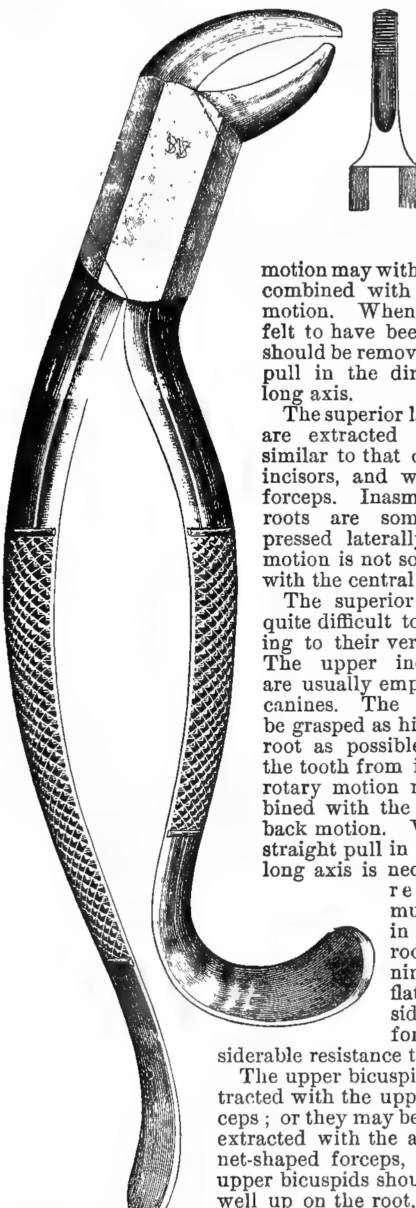

FIG. 3814.—Forceps No. 9. Incisor, Lower. Hawk-bill.

The superior lateral incisors are extracted in a manner similar to that of the central incisors, and with the same forceps. Inasmuch as their roots are somewhat compressed laterally, the rotary motion is not so important as with the central incisors.

The superior canines are quite difficult to extract, owing to their very long roots. The upper incisor forceps are usually employed for the canines. The tooth should be grasped as high up on the root as possible. To loosen the tooth from its socket the rotary motion must be combined with the forward-and-back motion. When loose, a straight pull in the line of its long axis is necessary for its removal. It must be borne in mind that the root of the canine is decidedly flattened on its sides, and therefore offers considerable resistance to rotation.

The upper bicuspids may be extracted with the upper incisor forceps; or they may be conveniently extracted with the alveolar bayonet-shaped forceps, No. 32. The upper bicuspids should be grasped well up on the root, and loosened by a side-to-side motion. Their roots being long and slender, great care is required to prevent their fracture. If the first upper bicuspid has a bifurcated root, it is often impossible to remove the tooth without breaking off the tip of one of the roots.

The first and second upper molars are extracted by forceps No. 18; one pair being suited for the right side and the other for the left. It will be noticed that the inner beak of each forceps is fashioned with a single concavity, it is thus fitted to embrace the inner buccal root of the first or second upper molar. The outer beak is divided by a longitudinal ridge into two concavities, while the tip of the beak is pointed in the middle. It is so made in order to embrace the two buccal roots of the first and second upper molars, and to conform to the depression between these roots. These forceps should be grasped in the palm of the hand, the thumb being brought into position between the angle formed by the two handles and the joint. The third and fourth fingers should be closed over the curve of the left handle. Owing to the divergence of the three roots of the upper first and second molars, considerable loosening is necessary before they can be extracted. This is effected by a side-to-side motion; as the outer alveolar plate is thinner than the inner, the main force should be applied in an outward direction. When the tooth is thoroughly loose in its socket, it can be removed by a downward and outward motion.

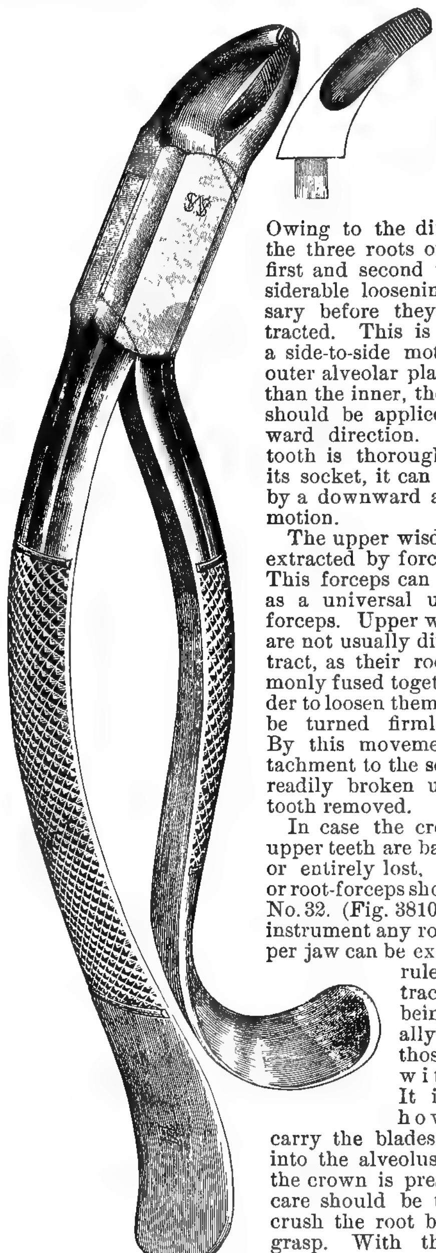

FIG. 3815.—Forceps No. 14. Incisor, Canine, or Bicuspid, Lower. For either side.

The upper wisdom tooth is extracted by forceps No. 10. This forceps can also be used as a universal upper molar forceps. Upper wisdom teeth are not usually difficult to extract, as their roots are commonly fused together. In order to loosen them they should be turned firmly outward. By this movement their attachment to the socket can be readily broken up, and the tooth removed.

In case the crowns of the upper teeth are badly decayed or entirely lost, the alveolar or root-forceps should be used, No. 32. (Fig. 3810.) With this instrument any root of the upper jaw can be extracted; the rules for the extraction of roots being substantially the same as those for teeth with crowns. It is necessary, however, to carry the blades farther up into the alveolus than when the crown is present. Great care should be taken not to crush the root by too firm a grasp. With the first and second upper molars it often happens that the three roots must be extracted separately.

In extracting the inferior teeth the patient should be situated much lower down than for extracting the superior teeth. The operator should stand at the patient's right side; oftentimes well to the back. The lower jaw should be grasped by the left hand, and supported from beneath by the palm and last three fingers, while the thumb and forefinger are placed within the mouth to retract the lips and tongue.

from the tooth to be operated on. The lower incisors are conveniently extracted by forceps No. 9. This may also be used for the right lower canine, and right lower bicuspids. The lower incisors, owing to the lateral compression of their roots, cannot be rotated in the process of loosening them. This must be accomplished by a forward-and-back movement.

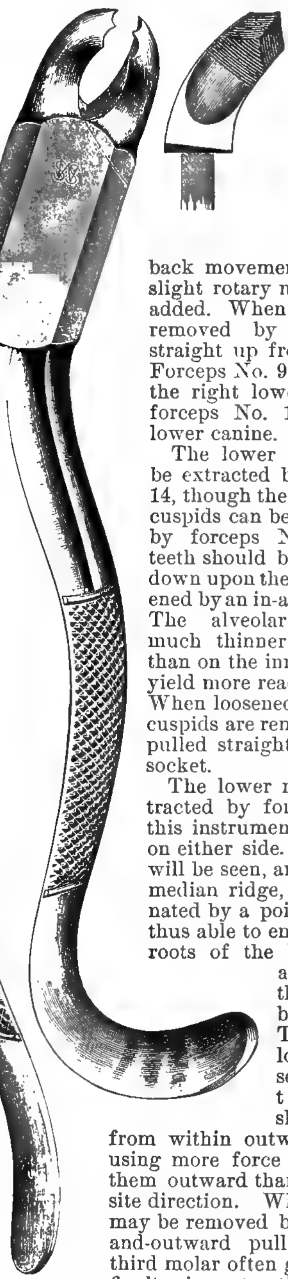

Fig. 3816.—Forceps No. 15. Molar, Lower. Either side.

The lower canines, owing to their very long roots, are often quite difficult to extract. They are to be loosened by a forward-and-back movement, to which a slight rotary motion may be added. When loose, they are removed by being pulled straight up from the socket. Forceps No. 9 are adapted to the right lower canine, and forceps No. 14 to the left lower canine.

The lower bicuspids may be extracted by forceps No. 14, though the right lower bicuspids can be well managed by forceps No. 9. These teeth should be grasped well down upon the root, and loosened by an in-and-out motion. The alveolar plate being much thinner on the outer than on the inner side, it will yield more readily outwards. When loosened, the lower bicuspids are removed by being pulled straight up from the socket.

The lower molars are extracted by forceps No. 15; this instrument can be used on either side. Its beaks, as will be seen, are divided by a median ridge, and are terminated by a pointed tip; it is thus able to embrace the two roots of the lower molars, and to engage the depression between them. To extract the lower first and second molar teeth, they should be rocked from within outward till loose, using more force when turning them outward than in the opposite direction. When loose, they may be removed by an upward-and-outward pull. The lower third molar often gives great difficulty in extraction, owing to the curve of its roots, which hook backward toward the ramus of the jaw. The forceps No. 15 may be used for this tooth. It must be loosened by a side-to-side rocking. Owing to the backward curve of its roots it cannot be lifted from its socket by a force exerted directly upward. In many cases forceps No. 98 is the best instrument with which to dislodge a lower wisdom tooth. It is applicable when the second molar is present. The blades of the forceps are closed between the second and third molars; by depressing the handles the third molar can be pried out of its socket, the second molar being used as a fulcrum. Care should be taken with this instrument that it does not slip and injure the back part of the mouth, and that the dislodged tooth does not fall into the pharynx. Injury to the second molar should likewise be guarded against, since this tooth might be loosened or dislodged in the extraction of the third molar.

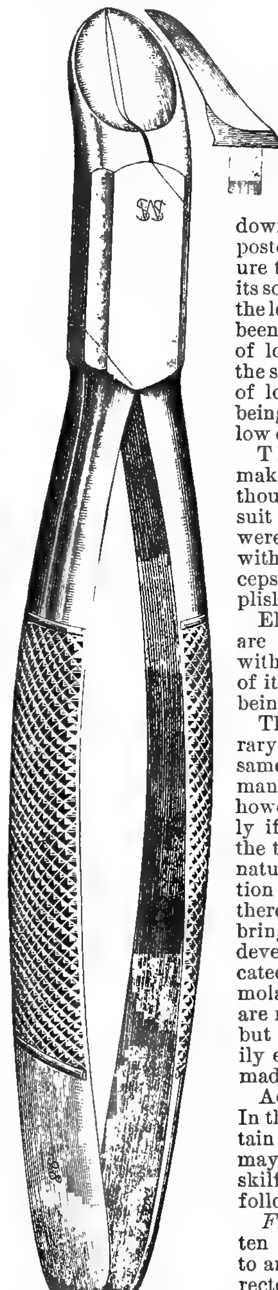

Fig. 3817.—Forceps No. 98. Dentes Sapientiæ, Lower. Either side.

Forceps No. 16 ("the cow-horn") can be used with advantage on the first and second lower molars. The beaks are shaped so as to follow down between the anterior and posterior roots, and by their closure to pry the tooth upward from its socket. To extract the roots of the lower jaw, forceps No. 52 have been designed. The extraction of lower roots is conducted after the same manner as the extraction of lower teeth with crowns, care being taken to apply the forceps as low down on the root as possible.

The instruments described make a good working set, although others might be added to suit individual peculiarities. If it were desirable to extract teeth with the fewest number of forceps, this result could be accomplished with Nos. 10, 15, 32, 52.

Elevators are often useful; they are straight and curved levers, with which a tooth is pried out of its socket, a neighboring tooth being used as a fulcrum.

The extraction of the temporary teeth is performed after the same manner as that of the permanent teeth. The operation is, however, much simpler, especially if performed at a time when the teeth are about to be shed by nature. In the premature extraction of the temporary molars there is always the possibility of bringing away the crown of the developing bicuspid, which is located between the roots of the molar tooth. Diminutive forceps are made for the temporary teeth, but temporary teeth can be readily extracted by the root-forceps made for the permanent teeth.

Accidents of Extraction.—In the extraction of the teeth certain accidents may occur; they may be unavoidable or due to unskilfulness or carelessness. The following are the more common:

Fracture of the Tooth.—This often happens, and is due usually to an excess of force, or to misdirected force, or to an insufficient grip upon the tooth. Cases occur, however, where fracture of the tooth is unavoidable; this is especially the case when the roots are misshapen and locked into the jawbone. When the tips of roots are, as the result of fracture, left in the maxillary bones, it is not always wise to remove them. Nature will usually expel them in due time.

Fracture of the Alveolus.—This occurs, to a limited extent, in every tooth extraction, and produces, as a rule,

no troublesome symptoms. By unskilfulness, however, a large portion of the alveolus surrounding a tooth may be crushed or fractured, and necrosis sometimes ensues.

Fracture of the Jaw may result from tooth-extraction. The fracture may be in the upper jaw, or in the body of the lower jaw. It may or may not imply fault on the part of the operator.

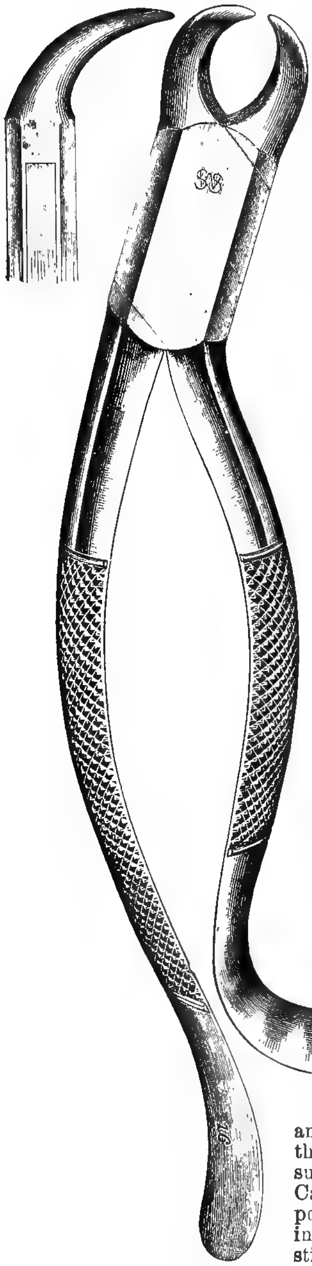

Fig. 3818.—Forceps No. 16. Molar, Lower. Either side. Cow-horn.

Dislocation of the Lower Jaw.—This usually happens with people whose jaws are loosely hung, and are in the habit of slipping out of the socket. If this tendency is known to exist, it is well to apply a roller bandage over the head and under the jaw before operating.

Removal of the Wrong Tooth.—This accident happens, as a rule, only to inexperienced or careless operators.

Removal of Two or more Teeth instead of One.—This may happen from an hypertrophy of the cement uniting adjoining roots below the gum. It may happen when the tooth to be extracted is overlapped by an adjoining tooth. It may happen also by the slipping of an extracting instrument, whereby a loose tooth is knocked out.

Laceration of the Mucous Membrane of the Gum.—This occurs to a limited extent in every extraction, but, through carelessness or unskilfulness, may be very extensive.

Falling of the Tooth into the Œsophagus or Air-passages.—A tooth will sometimes escape from the grasp of the forceps and be swallowed. From this accident no serious results are to be expected. Cases are now and then reported where a tooth falls into the larynx. This constitutes the most serious accident that can attend extraction. Such a tooth may be coughed up from the larynx, or it may enter the bronchial tubes, causing symptoms which are always serious and often fatal.

The inferior dental nerve has been crushed in the extraction of the lower wisdom teeth. In such cases a loss of sensation has occurred in the lower part of the face. Usually this passes away, though it may be permanent. In attempting to extract the roots of the upper bicuspids and molars they have been pushed into the antrum. When this happens the opening into the antrum should be enlarged and the roots removed.

Hæmorrhage after Extraction.—This is usually moderate in amount and of short duration. Such cases require no treatment. There are cases, however, where the hæmorrhage is so prolonged as to produce alarming symptoms, and in rare instances death has resulted. Great care should be taken in dealing with people having the hæmorrhagic diathesis. To control hæmorrhage after extraction the most successful method is to apply pressure to the bleeding parts. The bleeding usually takes place from the socket of the extracted tooth. The socket should be packed with cotton, lint, sponge, or any soft unirritating material. After packing the socket a compress of soft material, covering the socket and surrounding parts should be superadded. Upon this compress a gentle pressure should be maintained, either by the fingers or by the opposing jaw. An effective method of applying pressure after the socket has once been plugged is to soften a piece of gutta-percha in hot water and mould it to the affected region. Enough gutta-percha should be used so that the opposing teeth or alveolus can be embedded in it by the closing of the jaws. Let the jaws be closed and a roller bandage passed over the head and under the chin, and firm and constant pressure is secured upon the bleeding area.

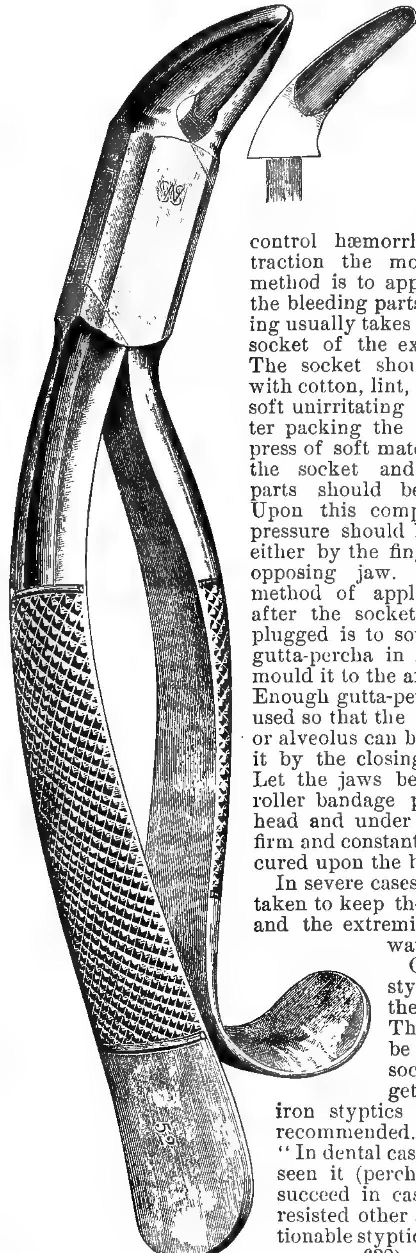

Fig. 3819.—Forceps No. 52. Alveolar, Lower. Either side.

In severe cases care should be taken to keep the head upright and the extremities artificially warmed.

Of the various styptics tannin is the most valuable. The powder may be applied to the socket on a pledget of cotton. The iron styptics are not to be recommended. Tomes says: "In dental cases I have never seen it (perchloride of iron) succeed in cases which had resisted other and less objectionable styptics" (Dental Surgery, p. 632). Tomes relies largely on the use of the matico leaf, softened in warm water and introduced into the socket as a plug, this plug being, if necessary, supplemented by a compress of cotton or lint. Very severe cases of hæmorrhage have been controlled by the use of the actual cautery. If this be used it should not touch the parts, but be held just near enough to bake them. If the cautery touches the tissues a fresh laceration is made by its removal.

In desperate cases of hæmorrhage internal remedies are

usually resorted to. They consist of tannic acid, gallic acid, and ergot.

General Considerations.—Haste in extracting should be avoided; the hand should never move faster than the eye can follow. The tooth should be under complete observation from the time it is grasped by the forceps till it is out of the mouth. The head of the patient should be firmly fixed, and under the control of the left hand or arm.

While considerable force is necessary to extract a tooth, the force should be so guarded and moderated as not to endanger surrounding parts. No jerks or sudden pulls are allowable.

The forceps should never grasp the crowns of teeth alone, as the crown will usually break off, leaving the root undisturbed, but should engage the tooth at its neck, or a little higher up if possible.

In extracting roots the beaks of the forceps should follow down between the root and its alveolus till a firm hold is obtained.

The cutting through of gum and alveolus with a root-forceps is not a desirable procedure, but is allowable in certain cases.

An excellent substitute for a dental chair is a rocking-chair with medium high back, a pillow thrown over the back forming a good head-rest.

William Henry Potter.

TENDON REFLEX. The tendon reflexes, properly speaking, include only certain muscular phenomena which are produced by the sudden stretching of tendons, as by a sharp blow or series of blows, under certain special conditions. Under the name of "deep reflexes," however, we find included with the so-called tendon reflexes proper a number of similar phenomena, which are produced by sharp blows or taps on the fasciæ, the ligaments, or the bones. As these phenomena are, so far as known, in nearly all respects similar to those produced by striking the tendons, all general statements made here may be considered to refer to them also.

When a sharp blow is struck upon the ligamentum patellæ in a healthy person, if the muscles be in a proper state of tension, it is immediately followed by a sudden rapid contraction of the quadriceps extensor femoris, causing the leg to be extended sharply upon the thigh, though only momentarily, as, the contraction ceasing, it immediately resumes its previous position. This is a typical "tendon reflex," which term is used to denote the sudden, rapid contraction produced in a muscle by a sharp blow delivered upon its tendon. As a general rule, in the normal physical condition, only the muscle whose tendon is directly irritated contracts, but in certain hypersensitive states this contraction may involve the neighboring muscles, and even be transmitted mechanically to the corresponding ones on the opposite side of the body. Under ordinary circumstances the "reflex" consists only in a single contraction of the muscle excited, but under certain abnormal conditions the stimulation may be followed by a series of contractions, constituting what is known as a clonus. The most common form of this is the ankle clonus (foot phenomenon), caused by the rapidly alternating contraction and relaxation of the calf muscles; and this will be considered more in detail later.

In healthy individuals only three "tendon reflexes" are found present with considerable constancy, the patellar reflex, that of the Achilles tendon, and the triceps reflex; though the presence of certain other reflexes (radial, ulnar, etc.) is not infrequent and cannot be considered abnormal. Of these the "patellar reflex" is so invariably present in health that its absence, except in old age, is always to be considered as a significant symptom; the triceps reflex and that of the Achilles tendon are very frequently present, but their absence in an otherwise healthy person cannot be held to have any special importance.

The patellar reflex is so far the most important of the "tendon reflexes," both from its value in diagnosis and because of the numerous experiments and investigations which have been made in regard to it, that it may properly be considered as the type of the tendon reflexes.

For this reason we will first describe it thoroughly, and will afterward pass on to the other "tendon reflexes," and point out any special peculiarities or differences which may be found in them.

PATELLAR REFLEX.—*Synonyms:* Patellar tendon reflex, Patellar tendon phenomenon, Knee reflex, Knee-phenomenon, Westphal's symptom, Knee-kick, Knee-jerk, Réflex erotulien, Phénomène du genou, Patellarsehnenreflex (Erb), Kniephänomen (Westphal).

Of these terms we prefer that of knee-jerk, as it implies no theory of cause and describes the phenomenon concisely, and we shall use it hereafter in this article instead of patellar reflex.

In order to obtain the knee-jerk, all that is required under ordinary circumstances is that the patellar tendon should be in a moderate degree of tension. To accomplish this most conveniently, the usual method is that the patient, sitting on a chair, should cross one knee over the other, letting the upper leg hang loosely without support at an angle of about sixty degrees. Or the patient may sit on the edge of a table or a bed, or, if a child, on a chair, letting both legs hang down without support. Commonly one of these methods is the readiest, but if the patient be stout, or for any other reason the knees cannot be readily crossed, it is advisable for the observer to support the limb to be tested on his arm, which is passed beneath it, while his hand rests on the patient's other thigh. When the patient is in bed, the condition of the knee-jerk can either be examined while the patient lies upon his side with the leg flexed at the above-mentioned angle on the thigh, or the thigh can be raised and supported, the leg being allowed to hang at the proper angle. In any of these cases it is well, when possible, if there be any question in regard to the presence of the knee-jerk, that one hand should be placed on the quadriceps extensor cruris, so as to feel the muscular contraction if it occur. Whatever position is adopted, it is important, in order to obtain a good knee-jerk, that the leg should not be held firmly in its position by the patient, either voluntarily or involuntarily, but that the muscles should be so far as possible relaxed, and the leg permitted to hang loosely. After the limb has been properly placed and the situation of the tendon patellæ determined, a sharp blow should be given about the middle of the tendon. The tips of the fingers, or, better, the inner edge of the hand, or in doubtful cases a percussion-hammer, may be used. Ordinarily the knee-jerk is obtained without difficulty through the clothes, unless very thick, but in questionable cases the blow should be delivered on the bare skin.

In this way, in the normal individual, the knee-jerk can usually be readily obtained. In some cases, however, even in otherwise healthy persons, a certain amount of difficulty is found, and in them Jendrássik's method of re-enforcement is useful. Some observers also have found that the knee-jerk is obtained more easily in certain persons by striking the tendon rather toward the inner edge.

History.—The attention of the medical profession was first called to the existence of this phenomenon and that of the ankle clonus, by Erb and Westphal, simultaneously, in articles published in the *Archiv für Psychiatrie*, in 1875, and from that moment these phenomena, especially the knee-jerk, became the subject of numerous scientific researches and investigations. Naturally, at first the diagnostic value of these symptoms received the most careful attention, and the importance of the absence of the knee-jerk in the recognition of tabes dorsalis, especially in the earlier stages, and of its condition as a means of differentiating various forms of disease of the nervous system, caused it at once to obtain recognition, and become the object of earnest study on the part of all the more advanced medical practitioners.

Physiology.—At the same time that its high value as a means of diagnosis and differentiation to the practising physician and surgeon was being practically recognized, its cause and the method of its production attracted interest, and became an object of inquiry to many of the most skilful investigators. This question was found not

to be by any means so simple as it might at first sight appear, and, indeed, up to the present time, the exact mechanism of the knee-jerk is undetermined.

From the very moment when it was first brought to the attention of the medical profession, the mechanism of this phenomenon became the subject of two contrary views, each supported by high authority, and with more or less unanswerable arguments in its favor. The difference between the opinions in regard to its origin held by its two discoverers is apparent even in the terms employed to designate the symptom. On the one hand, Erb, viewing it as the result of a simple reflex process, naturally gave it the name of tendon reflex, and as other tendons were found to act in a similar manner, this symptom became known as the patellar tendon reflex. Westphal, on the other hand, doubted from the very earliest whether this symptom was actually due to ordinary, simple, uncomplicated reflex action, and for this reason refused to accept the designation of tendon reflex until the exact nature of the occurrence could be better known, calling it meanwhile by the more general name of knee-phenomenon, which term has now given way, to a large extent, before the less cumbrous one of knee-jerk.

Immediately on the appearance of the articles of Erb and Westphal, investigations were begun to settle, if possible, the correctness of the opposing theories, and to determine the exact cause and method of production of the phenomenon. In the beginning the general tendency of medical opinion was undoubtedly in favor of the view that the "patellar phenomenon" was due to a simple reflex; even Gowers, afterward a strong opponent of this theory, writing in 1879, says, "the reasons for regarding it as a spinal reflex are strong." That this should be so was only natural, since it was in the first place, superficially, the most obvious and reasonable explanation, and, moreover, it was shown that any obstruction or defect in the reflex is followed by an immediate diminution or loss of the knee-jerk. *The integrity of the reflex arc is necessary to the production of the knee-jerk* (Tschirjiev and others).

Its external similarity, in many respects, to the ordinary reflexes was immediately apparent, and induced many to place it in this class until reasons to the contrary should be shown. These arguments naturally have much weight, and the upholders of the simple reflex theory have sought to strengthen them by others, such as the fact of the radiation of the knee-jerk to the muscles of the back, and the production of a contraction of the quadriceps extensor in the other leg at times.

On the other hand, Westphal and others have raised some very serious objections to this view, and in addition they have advocated another theory. Their argument is as follows: Although the fact be undisputed that the integrity of the reflex arc is necessary to the production of the knee-jerk, still it does not follow that the knee-jerk must in consequence be a simple reflex. On the contrary, that it is not so is shown by the fact that the latent period of the knee-jerk—that is, the time which elapses between the moment of the blow and that of the subsequent muscular contraction—is much shorter than that of any known reflex, and more resembles in this respect the result of direct muscular excitation. It is now generally admitted that the latent period of the knee-jerk is usually from 0.02 to 0.03 second, while that of an ordinary reflex, *e.g.*, skin-reflex, is much greater, 0.12 to 0.14 second. Eulenburg gives the average of his experiments in adults as 0.03226 second. In children it may rise as high as 0.04389 (De Watteville). In this relation Eulenburg's comparative tracings of skin-reflexes and knee-jerks are of much interest.

In regard to the radiation of the knee-jerk to the muscles of the back, and to the quadriceps extensor cruris of the opposite leg, this has been conclusively proved, by the experiments of Prévost and Haller, to be due to the direct vibration conveyed through the bones of the pelvis, inasmuch as it still exists after section of the spinal cord and of the posterior nerve-roots.

The theory of those who are opposed to the simple reflex view is that the knee-jerk is dependent upon the tonicity of the muscle. They say that under normal circumstances a certain amount of tonicity in the muscle—a muscle tonus—always exists; that this, however, is destroyed by injury or destruction of the reflex arc, and that it is due to the loss of muscle tonus that we are unable to obtain the knee-jerk in such cases. Westphal considers three conditions necessary for the knee phenomenon: (1) Tonicity of the muscle; (2) tension of the muscle; (3) elasticity of the ligament. If either of these is lessened beyond a certain point, the knee-jerk is likewise lessened or abolished.

The strongest and most valid objection to this theory is that it presupposes the existence of a muscle tonus. Until we have some definite evidence in favor of its existence, it seems scarcely justifiable first to assume it and then to base a theory upon this assumption.

Pathology.—The pathology of the knee-jerk may be briefly stated. Anything which interrupts the reflex circuit will prevent the appearance of the knee-jerk. The reflex arc for the knee-jerk, beginning in the sensory fibres running in the anterior crural nerve, passes through the posterior nerve-root into the spinal cord between the second and third lumbar vertebræ, and thence returns to the quadriceps extensor femoris through the motor fibres of the anterior crural. In 1877, Schultze and Fürbringen showed that after section of the crural nerve percussion of the patellar tendon was unable to produce contraction of the extensor femoris, although this muscle responded to direct excitations. It is well known that section of the lumbar posterior nerve-roots produces the same result. In the spinal cord, in man at least, the circuit probably passes through the posterior columns. At any rate, it is certain that the knee-jerk disappears, as a rule, in diseases of the posterior columns, while it is increased in lateral sclerosis. At the present time clinical evidence favors the view that it is especially disease or injury of the portion of the posterior columns lying on the border of the lateral columns that causes the abolition of the knee-jerk.

Clinical Value and Symptomatology.—The value of the condition of the knee-jerk as a means of diagnosis has been much disputed, but there is now no longer any question that it is of great importance when its signification is properly understood. In certain cases even, the probability of the existence of certain conditions of the spinal cord can be determined by the character of the knee-jerk alone.

The knee-jerk may be exaggerated, or it may be diminished or absent.

Exaggeration of the Knee-jerk.—The knee-jerk may be rendered more active physiologically in many ways. It has been shown by Jendrássik, Weir Mitchell, and others that when the knee-jerk coincides in time with some other action of the body, or even with certain sensations or emotions, its action is increased; it is *reinforced.* This reinforcement is produced constantly by numerous slight conditions, so that in the healthy normal person the knee-jerk is constantly varying slightly. Thus, Lombard says: "The extent of the normal knee-jerk is continually undergoing change. The average knee-jerk varies in amount at different times of day, being as a rule greatest in the morning, soon after breakfast, and being very much less at night." The decline during the day is irregular, the knee-jerk increasing after each meal. In this case the knee-jerk may be considered as being strengthened by the general physical condition; but it is also momentarily reinforced by any simultaneous action, as motion of the arm, crying, laughing, speaking, or by the sensation of a loud sound. In certain cases this effect is mechanical, due to tension of the muscle. Jendrássik first turned this fact to a practical use by suggesting that in cases where the knee-jerk was diminished, or apparently absent, the patient should be told to clinch his hands and pull on them as strongly as possible, and that while he was thus engaged the knee-jerk should be tested. This procedure acts to increase the knee-jerk in two ways: first, probably as actual reinforcement; secondly, by distracting the patient's attention and preventing him from keeping his limb in that condition of tension which hinders or prevents its movement. As a general

rule we may consider that the stronger the reinforcement is, the more marked will be the knee-jerk.

The knee-jerk is also increased by certain bodily conditions. It is increased by chronic fatigue, and in almost all cases of weakness and irritability of the nervous system, from whatever cause. Thus, we find it exaggerated in nearly all cases of neurasthenia, of spinal irritation, of hysteria—in fact, in all forms of functional nervous disorder where irritation or irritability may be presumed to exist. It is found increased in all cases of general weakness of the nervous system—nervousness—to a greater or less extent, and hence appears frequently—in fact, as a rule—to be so in persons convalescent from severe disease, and in many cases of chronic disease, phthisis, etc.

It is also pathologically increased in certain irritative or inflammatory lesions of the central nervous system. It is thus exaggerated in certain stages of cerebral meningitis and in spinal meningitis. But the most highly developed pathological forms of knee-jerk (knee-clonus, knee-tetanus) are found principally in certain definite lesions of the spinal cord. In lateral sclerosis the knee-jerk is almost typical in its exaggeration, and, *vice versa*, when the knee-jerk is increased beyond a certain point it strongly suggests the presence of disease of the lateral columns. In no other disease does it reach the extent which it does in this, or is it capable of being so easily excited.

Increase in the knee-jerk occurs in all cases whenever the access of voluntary innervation to the muscles is hindered, however slightly.

It is especially increased in cases of transverse myelitis when this occurs in the dorsal or cervical regions, while the same affection in the lumbar region abolishes it.

It accompanies not only central organic lesions, but also hysterical. It is found even with lesions of the pyramidal tracts which produce no perceptible paralysis.

The knee-jerk is likewise increased by causes which increase the general irritability of the spinal cord. Thus, we find it exaggerated in tetanus and in poisoning by strychnia.

It should, moreover, theoretically, be capable of increase through pathological conditions of the muscle, tendon, etc., but in regard to this we have as yet no definite knowledge.

Diminution of the Knee-jerk.—In the normal, healthy individual the knee-jerk is, in a certain number of cases, only to be obtained with care and difficulty, and is decidedly below the average. This seems to be idiopathic or constitutional. Whether this can absolutely reach the point of absence without the existence of any disease or disturbance in the nerves or spinal cord, while the proper conditions exist in the muscles and tendon, seems doubtful. For practical purposes, however, we may admit the existence of a small number of such cases, but they are so rare, that the value of the absence of the knee-jerk as a diagnostic symptom is not thereby essentially lessened. Physiologically, the knee-jerk is diminished by conditions of temporary fatigue. It is sometimes difficult to obtain it in infants and children, and it is said to be often absent in old age.

Pathologically, absence of the knee-jerk may be caused by anything which breaks or interrupts the current of the reflex arc. It may even be produced by causes which give rise to no appreciable organic lesion, as stretching of the anterior crural nerve. It is caused frequently by neuritis of the anterior crural or its branches, and this is probably the cause of its absence in certain cases after diphtheria, in diabetes, in phthisis, and after typhoid fever and other acute diseases. For this reason it is apt to be absent in multiple neuritis of whatever origin, whether idiopathic, syphilitic, toxic (due to alcohol, lead, or arsenic), or accompanying general paralysis. It may also, of course, be produced by injuries, especially section of the anterior crural. Likewise, it may be caused by anything which prevents the transmission of impulses through either the anterior or posterior nerve-roots (injuries, tumors, etc.). As previously stated, the path which the sensory impulse takes in the spinal cord after leaving the posterior nerve-roots is not yet wholly settled, but it seems to be especially connected with the external portions of the posterior columns. At any rate, disease or destruction of the posterior columns of the spinal cord in the lumbar region produces absence of the knee-jerk. This is one cause of its absence in tabes dorsalis—sclerosis of the posterior columns—a disease in which the absence of the knee-jerk has become a most important diagnostic symptom and is sometimes an early one. But the knee-jerk may also be abolished by any other cause equally affecting the posterior columns, even though it do not present the clinical picture of tabes. Thus, it may be absent in transverse myelitis in the lumbar region of the cord (always is, if the myelitis be complete), in certain forms of diffused myelitis, in disseminated sclerosis, and in tumors or other growths affecting the spinal cord. Injuries and sections of the cord in this region, respectively, may and must abolish it. But the posterior columns are not the only part of the cord the affection of which seems to produce abolition of the knee-jerk. It is also absent in almost all cases of anterior poliomyelitis. In *infantile paralysis*, indeed, the diagnosis is always rendered doubtful until after long examination, if the knee-jerk be present.

Whenever the knee-jerk is totally absent for a considerable period without other symptoms, it points toward disease of the posterior columns.

The knee-jerk may likewise be diminished or abolished by cerebral influences. This is the case in opium narcosis, and in all forms of coma.

It may also be diminished or caused to disappear entirely from purely mechanical causes. The tension of the quadriceps extensor femoris may be rendered so great that it is unable to contract readily. This may occur from the too great flexion of the leg on the thigh, or from some pathological condition in the muscle. Again, the tendon or the muscle may be so relaxed that no reaction can be obtained by tapping the tendon, as occurs when the leg is fully extended on the thigh. Lastly, it is said that in cases where a mass of fat is situated directly beneath the tendon this prevents its vibration, and in such case no knee-jerk can be obtained (Westphal).

Ankle Clonus.—Next to the knee-jerk, by far the most important of the deep reflexes, from a diagnostic point of view, is that caused by the stretching of the Achilles tendon, and usually known as the Achilles tendon reaction, or in the more advanced stage as the ankle clonus (foot-phenomenon of Westphal). Like the knee-jerk, it was first brought to the notice of the medical profession by Westphal, and Erb, simultaneously, in 1875, and since then has been the object of much study. The Achilles tendon reaction is almost always present in the healthy individual, and may be developed by tapping the Achilles tendon sharply with the fingers or a percussion hammer while it is in a state of tension. In consists in a single contraction of the external muscles of the calf (gastrocnemius and soleus), and is to be carefully distinguished from the ankle clonus, which is a series of rhythmical contractions of the same muscles, and bears the same relation to it that the knee-clonus does to the knee-jerk.

The ankle clonus is produced usually by the sudden and forced flexion (dorsal flexion) of the foot upon the leg, which causes the stretching of the Achilles tendon, and it consists in rhythmical contractions of the calf muscles, which cause involuntary extension of the foot. In severe cases these contractions may be developed to a high degree, and in most cases where ankle clonus exists the contractions will continue so long as the tendon is kept tense. As a rule, with the exception of one or two weak contractions, the clonus ceases immediately on the cessation of the forced tension of the tendon, but the contractions can be made to cease instantly by extending the foot and thus relaxing the tendon. Ankle clonus does not occur in the healthy individual under ordinary circumstances, but it may be produced if desired. If, for example, anyone while sitting, the leg being at an acute angle with the thigh, will let the foot rest upon the ball of the toe, the heel being raised and unsupported, and

will then voluntarily raise and lower the heel, "imitating the movements made when an infant is dandled on the knee," he will soon find that the movements are continued involuntarily, and cannot be stopped without a distinct effort. The ordinary method, however, of testing for ankle clonus is for the physician to grasp the foot firmly with one hand, while the patient's leg is almost fully extended upon the thigh, and to suddenly and forcibly flex the foot dorsally upon the leg. Tension of the Achilles tendon is thus best produced.

The contractions of the muscles in ankle clonus are, as before stated, rhythmical, and, according to Gowers, occur at the rate of from six to ten per second.

An exaggeration of the tendo Achillis reaction may be obtained under the same conditions as exaggeration of the other deep reflexes. The foot clonus may be obtained in slight chloroform narcosis, but not under ether or nitrous oxide. It is also present for a short time after certain epileptic attacks. A slight clonus also occurs at times in cases of great functional nervous irritability, toxic or other (tobacco, alcohol), but this is usually temporary. Gowers believes that, when "a uniform clonus can be obtained by simple flexion of the foot," it "is always pathological, always indicates grave nutritive changes in the spinal cord, and that there is, in most cases in which it can be obtained, actual degeneration in the fibres of the lateral columns."

The diagnostic value of the ankle clonus consists in the fact that it is only present when the deep reflexes are much exaggerated, and may be regarded usually as a sign of some affection or lesion of the corresponding lateral column of the spinal cord. It occurs in its most typical form in sclerosis of the lateral columns, and it is often present on the affected side in cases of cerebral hemiplegia, in which case we are justified in presuming that an affection of these columns exists. It naturally occurs also in cases of transverse myelitis, and in tumors of the cord or its membranes where these columns are affected. It is even present in amyotrophic lateral sclerosis, where both the lateral and the posterior columns are involved.

It is scarcely necessary to state that the spurious or voluntary foot clonus, which sometimes is found in hysteria, should be carefully distinguished. This latter is produced by the voluntary contraction of the calf muscles as the patient pushes the foot against the physician's hand, and does not, like the true clonus, begin immediately on the forced extension of the tendon, but some seconds after.

Other Deep Reflexes.—With the exception of the knee-jerk and the Achilles tendon reaction, the so-called deep reflexes of the upper extremity, the triceps, the ulnar, and the radial, of which the last two are periosteal, are the only ones which occur in any large proportion of healthy persons, and these have no special clinical significance. Many other deep reflexes, however, occur under abnormal or pathological conditions. Under the same circumstances which produce exaggeration of the knee-jerk or of the Achilles tendon reaction, muscular contractions from the tension of other tendons begin to appear in the corresponding muscles, and various similar phenomena from the tapping of the periosteum or fascia in various parts of the body. Thus, as regards those produced from tendons, reactions may be obtained from those of the biceps, the supinator longus, the radial extensors, the flexors of the fingers, etc., in the upper extremities; and from those of the adductors of the thigh, the gracilis, the biceps femoris, the tibialis anticus, the tibialis posticus, and the peroneus longus in the lower extremities.

Of the periosteal reflexes the best known is the "front tap," or "tibial tap," which terms are used to denote the sudden contraction of the quadriceps femoris produced by a gentle blow on the front of the tibia, near its middle. This usually exists under the same conditions as the ankle clonus. The ulnar and radial reactions mentioned above are obtained by tapping the lower ends of the ulna and radius, which causes respectively contractions of the triceps and biceps. Many other periosteal reflexes may occur, and in some cases even moderately distant muscles may react (remote reflexes), as in the scapular and clavicular reflexes, where, on tapping the spine of the scapula, a contraction is caused in the deltoid, and the biceps reacts to a blow on the sternal end of the clavicle. Contractions of the chest muscles may sometimes be produced by striking the costal cartilages or the ribs, while blows on the transverse processes of the cervical vertebræ may cause contractions of the muscles of the upper arm, and on those of the lumbar vertebræ contractions of the glutei and adductors of the thigh.

When the excitability of the deep reflexes is greatly increased, we even begin to find other forms of clonus, and this is especially common in cases of late hemiplegic rigidity. Thus a wrist clonus may be produced by a sudden and forcible hyperextension of the wrist, or a toe clonus may exist, caused by rhythmical contractions of the abductor and flexor brevis pollicis. Gowers also describes a lateral ankle clonus from contraction of the peronei, which can be produced by passive pressure of the foot inward.

Spinal Epilepsy.—Under this name is known a condition in which the whole lower extremity shakes *en masse*, forcibly and violently, when moved passively, or even when touched. This is considered to be due to an increase in the excitability of the Achilles tendon greater than that which exists in ankle clonus (Möbius), or to "combined contractions due to stimulation of some of the superficial and deep reflexes" (Ross). It only occurs in cases of degeneration of the lateral columns of the cord, and is perhaps most frequently to be observed in paraplegia from Pott's disease, or in other forms of transverse myelitis.

Paradoxical Contraction (Westphal).—This phenomenon may be considered roughly as the opposite of the ordinary tendon reaction. It consists in the contraction of a muscle caused by the passive approximation of its extremities. It is best known in the tibialis anticus, in which it may be produced in the proper cases by the rapid dorsal flexion of the foot. In these cases the foot remains, after the pressure has ceased, firmly fixed in the position of dorsal flexion, and may be held so many minutes. Other muscles sometimes assist the tibialis, as the extensor communis digitorum and the extensor brevis pollicis. This form of contraction has also been observed in the biceps femoris, and may even occur in the muscles of the upper extremity. It is found principally in those muscles of the extremities in which the "tendon reflexes" are rare and difficult to obtain, and, on the other hand, does not seem to occur in those, like the quadriceps femoris, in which they are ordinarily present. Paradoxical contraction is said to be usually associated with paresis of the lower extremities. It occurs when the deep reflexes are absent or normal, and even when they are somewhat exaggerated; but it cannot occur, at least in the tibialis, when an ankle clonus exists. It has not been observed where there is an excess of cutaneous sensibility. This phenomenon is found only in disease. It has been observed in cases of combined sclerosis of the posterior and lateral columns, in paralysis agitans (Westphal), and in hæmatomyelia (Ross).

TENDONS, DISEASES AND INJURIES OF. The tendons are not so often the seat of surgical disease as are their sheaths, and some consideration of the diseases of the latter must unavoidably be included in a description of the affections of the tendons themselves.

Necrosis of tendons may follow injury or inflammatory conditions of the surrounding tissues, or may be a part of a general necrosis. This is readily understood when one considers that the tendons are organs of rather low vitality, and that their blood-supply is easily cut off. This necrosis may prove very troublesome and exhausting in an already depreciated condition of the system. The story of such a case, which occurred in the practice of Dr. E. M. Culver, of New York, may not prove uninteresting: An old lady, seventy-three years of age, was suffering from senile gangrene involving the great toe. The sphacelus had come away, leaving a clean granulating surface, but in the sole of the foot, opposite the metatarso-phalangal joint, was an abscess. Slight manipulation of this abscess caused a considerable quantity of fetid pus to escape through the ulcer. Incision of the abscess showed that the necrosis of the flexor tendon of the toe had been its exciting cause. The process continued, and several abscesses were opened along the course of the tendon before recovery ensued. Although so extreme a case from this cause is not common, the death of tendons is not rare after contused wounds, and as a sequel of suppuration in the tendon-sheaths. After necrosis has occurred, the tendon is seldom, if ever, reformed, and the function of the part is permanently impaired. The condition is not one which permits of special treatment for the tendons, except prompt evacuation of all collections of pus, and the removal of the necrotic tissue as fast as it separates from the seemingly sound parts.

Tumors do not often involve the tendons, but they may do so. Carcinoma and sarcoma develop in this tissue only through extension by contiguity, and do not form there by metastasis. Occasionally small fibromata develop upon the tendons, and give rise to more or less annoyance. They are usually quite small, and do not often attract much attention unless they interfere with the proper action of the tendon, or are painful by being so situated that they are subject to pressure. These fibromata may be felt as small, hard lumps beneath the skin, adherent to, and moving with, the tendons. The flexors of the fingers are their most usual site. They are, as a rule, neither painful nor tender, nor do they increase rapidly in size, nor incline to become adherent to the surrounding tissues. These fibromata are said to tend to become sarcomata when they are of large size or rapid growth. This tendency should lead one to exercise caution in refusing to operate upon a tumor that seems to be innocuous. Should it become necessary to treat these growths, they may be removed, provided antiseptic precautions are taken, and care is observed that the tendon does not become adherent to the sheath at the part from which the tumor was removed. Gummata may form upon tendons, but their identification is involved in their history and in the recognition of concurrent lesions, as well as in their disappearance after antisyphilitic treatment with mercury and the iodides. For a description of the cystic tumors springing from the tendon-sheaths, see article Ganglion (Vol. III., p. 297).

Acute tenosynovitis (inflammation of the sheath of a tendon, thecitis) may follow strains or wounds, or may complicate syphilis, gonorrhœa, or rheumatism. Occasionally such an attack is seen during the course of one of the continued fevers. The severity of the attack depends, generally speaking, upon the presence or absence of suppuration; the presence of pus rendering the affection much more grave. It will be found convenient to speak of suppurative tenosynovitis separately.

Non-suppurating Tenosynovitis.—In the traumatic cases of acute non-suppurating tenosynovitis, where no wound has occurred, the disease may follow prolonged or repeated muscular efforts; or a single severe strain, as in giving a hard blow with the fist, or a strong push; or it may follow contusion. Dr. G. B. Phelps, of New York, whose experience has been large in this class of cases, informs me that he has observed that tenosynovitis most often attacks those who change from an accustomed to an unaccustomed form of hard labor, and those who have been idle and have just obtained work. He thinks that it comparatively seldom follows a single severe effort. It attacks most often the flexor group in the wrist; though it is also seen in other localities, notably the extensors of the fingers at the wrist, the tendons about the ankle, and the long tendon of the biceps cubiti. The symptoms which point to tenosynovitis are pain and tenderness, with some swelling, along a tendon-sheath. This pain will be increased by active or passive motion of the tendon. The disability of the part is complete on account of the pain; or, rather, motion in the part controlled by the tendon will be avoided and the part will be held in a position most favorable for rest. In addition to this, there may often be felt a peculiar rustling feeling of crepitation, difficult to describe, but which resembles in some degree the sensation produced by subcutaneous emphysema. The sensation may, perhaps, be conceived, if one has a good imagination, by likening it to feeling crepitant râles. This condition is explained by the pathological condition which exists. The changes which occur are those of all serous inflammations: Congestion, followed by serous, and subsequently fibrinous, exudation. These cases usually do well, though occasionally recovery takes place with an adherent tendon. There is but little tendency to become chronic, and the inflammation seldom becomes purulent unless by infection from an open wound.

The duration of the disease is from a week to a month, depending upon the severity of the attack and the constitutional ability of the patient to recover from any inflammatory disorder. Constitutional treatment is not usually demanded in these cases when of traumatic origin. Opium may be needed to relieve the pain, and an occasional laxative may be indicated. Rest, pressure, and counter-irritation are the chief factors in the treatment of acute tenosynovitis. Rest is secured by splints. Pressure evenly applied and extending above and below the site of the lesion is invaluable. This is well obtained by the application of a "cotton dressing," which consists of a tolerably thick layer of cotton-wool firmly bandaged in place. The rubber (Martin's) bandage may be used, if it is well borne, though an ordinary muslin roller bandage is commonly quite sufficient. Counter-irritation in the milder cases, uncomplicated by wounds, is almost always of use. Iodine is a common application for this purpose, and may be used in the form of the officinal tincture, or better, perhaps, in that of the ointment. This is perhaps as good as any of the milder counter-irritants. If the pain is severe the mildly astringent and anodyne lead and opium wash (Lotio Plumbi et Opii, U. S. Ph.) will often serve a good turn, and may be applied hot or iced, as desired, until the pain is nearly or entirely relieved. Hot or cold water applications are often advised under the same circumstances, until a more permanent dressing can be borne. Moderate passive motion may be used if the attack is prolonged and there seems to be a tendency for the tendons to form adhesions. The rheumatic, syphilitic, and gonorrhœal forms of tenosynovitis require treatment directed to the causal disease, in addition to that above described.

Suppurative tenosynovitis usually follows wounds of the tendon-sheaths which have become infected; but may occur after very slight injuries in the neighborhood of the tendon; and, sometimes, it seems to occur after the milder form without open wound. The trouble, once started, resembles cellulitis in its course. It may be entirely local or may involve, in a very short time, a whole member. The disease is characterized by very severe

pain of a throbbing character, by fever and occasional chills, and by marked prostration, in addition to the symptoms already noted as characterizing the milder type. The skin is reddened in these cases, and the local tenderness is more marked than in the non-suppurative cases. The tendency of the disease is toward destruction of more or less of the tissues attacked, and recovery is often rendered incomplete by the presence of unyielding tendons, by unsightly scars, and by the contractions resulting. In some cases even amputation is necessary to save life, so virulent is the septic attack. The treatment is the same as that of suppurating cellulitis, viz., free evacuation of pus and clean after-treatment. As soon as the presence of suppuration in a tendon-sheath seems assured, it is necessary to freely incise the sheath and drain the part as much as may be necessary. The tendons are liable to necrose in these cases, and often considerable deformity may result in this way.

Calcification of Tendons.—Old people who have been subject to rheumatic attacks may have deposits of lime in one or more of the tendons. This occurs near stiffened joints in most instances. The patellar tendon, above or below the bone, is a frequent site for such a condition. These tendons are especially liable to rupture by muscular violence. It is not a condition which admits of active treatment.

Chronic Tenosynovitis (hygroma, compound ganglion) is a disease characterized by gradually increasing, painless swelling, more or less loss of power, and the development of certain small fibrinous masses in the distended tendon-sheath. These masses are known as rice-bodies or melon-seed bodies. The affection may follow the acute form, or may be of gradual development without any apparent cause. The etiology of chronic tenosynovitis is rather obscure; it is often tubercular and sometimes syphilitic or rheumatic in origin, besides, as we have seen, arising from trauma through the acute form. It most commonly affects the flexor tendons in the forearm and hand, in which situation the swelling will be seen above and below the annular ligament, and divided by it into two portions. Pain and tenderness are not often marked in this as in most chronic inflammations. The disability is of gradual development and is not usually complete; the common experience is, that prolonged effort weakens the part so that it incapacitates the patient for his usual work. The tumor is fluctuating, and the wave, started from either pouch of the sheath, may be felt to pass into and distend the other. The rice-bodies may sometimes be felt to interrupt the regular current of the distending wave as they pass through the narrower portion of the sac beneath the annular ligament. The diagnosis is not usually difficult in these cases, though, if there has been spontaneous or operative opening of the cyst, with pouting granulations and serous discharge, the appearance may simulate that of a malignant growth or a carious joint.

Left alone, the disease does not tend to recovery. There are reported many cases of failure to cure, of anchylosis from tendon adhesion, and even some of caries of the carpal bones, and of amputation to save life after operation; but when the operation is performed with antiseptic precautions many cases may recover quickly and permanently. The cure demands treatment by operation. Benefit does not often follow local measures, nor the injection of the cyst. The treatment which is usually the most successful is that of opening the sac above and below the annular ligament, thoroughly washing out the cavity, and clearing it of the rice-bodies. The surfaces may require to be scraped with a sharp spoon, to detach some of the fibrinous fungosities. The entire cavity should then be drained by a tube passed through both openings, the one in the palm and the other in the forearm. A splint is, of course, a necessary part of the dressing. If the splint can be so arranged as to avoid its removal for the subsequent dressings, much pain is avoided during the first few changes. The other methods by which these chronic inflammations have been treated need hardly occupy our time. Evacuation by a cannula and drainage, the splitting of the whole length of the wall (including annular ligament), and setons have all been of use, but do not seem to offer greater advantages than the operation mentioned.

Dislocation may follow severe strains of the tendons. This occurs rarely in any locality, but perhaps most often at the ankle, where the anatomical relation of the tendons to the malleoli is such as to permit the accident. It also occurs as a complication of fractures and of dislocations of the bones. The symptoms are pain, tenderness, and disturbance of function, with, usually, deformity. The diagnosis may be uncertain, unless the deformity caused by the absence of the tendon from its usual site can be detected. This may be obscured by the thickness of the overlying tissues and by swelling after injury. At the ankle, where the injury most often occurs and where the results of dislocation would seem most serious, the displaced tendons may easily be felt. The outlook is not ultimately unfavorable, as the probability of the tendon reassuming its function in its new locality is considerable, even when attempts at retention after reduction fail. Manipulation seldom fails to reduce the displaced tendon, but its retention is often a matter of great difficulty. This may usually, however, be accomplished by pads and snug bandaging, perhaps with an elastic bandage. The part must be immobilized for a considerable time, and its use prohibited until the retaining bands are strongly re-formed. Tenotomy may be necessary to prevent muscular action throwing the tendon out before it has become solid in its bed.

Rupture of Tendons.—This accident occurs with surprising frequency when one considers that the sudden violence of machinery accidents, involving great strain of tendons, is more apt to tear out the tendon entire than to rupture it. This is shown in the case of evulsed fingers, where the separation occurs between the muscle and tendon, and not in the body of the tendon. Sudden muscular action is usually the cause of the accident. As a rule, the tendons that break are the seat of some degenerative lesion, and for this reason the accident is more common in persons past their physical prime. The tendons most often ruptured are the long tendon of the biceps cubiti, the tendon of the quadriceps extensor cruris (above or below the patella), the tendo Achillis, and the tendon of the plantaris muscle. The occurrence of such an accident is denoted by a sudden snap, often both felt and heard by the patient, and by pain and loss of function. A day or two later, ecchymosis under the skin may be present. The defect in the tendon may be felt in the case of a superficial tendon, like the tendo Achillis. A cramp-like bunching of the muscle may also be noted, and may be of service in confirming the diagnosis. The result of the injury is not usually serious, with proper treatment. Union takes place by the organization of the clot which forms, as in subcutaneous tenotomy, and after a time the appearance of the tendon is normal. The treatment after the rupture of tendons is entirely by position and such aid as can be secured by bandaging in such a manner as to relax the contracted muscle. For example, the tendo Achillis being ruptured, the treatment should consist of apposition of the ends as nearly as possible by bandaging the leg firmly from above downward, strong extension of the foot, and fixation in an immovable splint.

Wounds of the Tendons.—The wounds of tendons are of the same nature as are wounds in general. They may be the result of an accident, or may be made by the surgeon. Such wounds may be classified as open or subcutaneous; operative wounds falling, in most cases, in the latter class. The wounds may be further classified as incised, punctured, or contused; as transverse or longitudinal; clean or infected; and complete or partial, according as the entire tendon or a part of it is divided. The usual condition which demands the surgeon's attention is a transverse incised wound, more or less unclean, in which one or more tendons have been divided. Such wounds are perhaps most common in the forearm, about the wrist-joint, and in this location the number of tendons involved may be quite large. To a less degree, the tendons passing the ankle and knee-joints are liable to be cut. Knives,

sharp tools, and glass are the usual instruments with which the wounds are made. After the complete division of a tendon the symptoms are complete loss of function, retraction of the tendon, and more or less "bunching" of the muscle of which the tendon is a part. The loss of function is not complete with partial division. Longitudinal and punctured wounds do not often occasion complete disability or loss of function, unless inflammation in the sheath of the tendon be present. Even after the original wound is healed the detection of the cut tendon is usually easy. The divided end of the tendon will be involved in the cicatrix, which will be drawn by the contraction of the muscle. Sometimes the defect may be felt in the tendon, and occasionally the contracted muscle may be prominent.

A cut tendon, if left to itself, is not likely to heal with restoration of function, for the newly formed part may not entirely fill the gap between the divided ends; and, furthermore, adhesions are likely to take place. Inflammation may in the same way lock the part. Secondary operations are often of use, and if the tendon is a functionally important one, they should be attempted. Contused and infected wounds of tendons, when severe suppuration occurs, are apt to be followed by sloughing of the tendons. Amputation of a small member is sometimes advisable, when permanent stiffening has occurred on account of a tendon-wound, in order to get the part out of the way of a more useful member which may do its work. Subcutaneous injuries and uninfected open wounds almost always unite without loss of function, when the parts can be approximated and retained for a sufficient time to allow union.

In the case of recent wounds, in which tendons have been divided, the question of their immediate suture is to be decided upon general surgical principles. If the wound is clean, or susceptible of being made surgically clean, it will, in most cases, be best to unite the divided ends of the tendon. In granulating wounds the same is usually true. Suppurating wounds will need preparatory treatment to render them aseptic. When the tendon is only partially divided the use of sutures is not commonly demanded, as the divided fibres will usually unite sufficiently without operation. When a number of tendons are divided it is difficult to unite the distal ends to their respective muscles, because of the disturbed anatomical relations and the similarity of one tendon to another. This is especially true at the flexor side of the wrist. This does not seem to be essential, however, as nature seems to permit the muscle to serve in its new duty without destruction of the co-ordinating power. Rest is very essential to a part after these operations, and should be secured by a splint so arranged as not to require removal for the dressings. The splint should be retained until the union is firm—usually for from three to eight weeks. Drainage, too, must be very carefully looked after, for often sutured tendons survive suppuration in the wound when the products of the inflammation are well drained away.

The Suture of Tendons.—In suturing tendons the most accurate details of antisepsis should be followed, because the least suppuration will often mean the undoing of all the work, plus the danger of suppurative inflammation extending in the sheath of the tendon. Complete general anæsthesia is commonly best, as it enables the operator to work at his leisure, and relaxes the muscles of the patient. To bring the retracted tendon into view, the part should be relaxed as much as possible by position. A rubber bandage (Esmarch's), applied from above downward over the muscle, may advance the tendon sufficiently to enable one to draw it into view with forceps. Often it will be found advantageous to enlarge the original wound, both to afford space for working and to facilitate the discovery of the tendon. The tendon may be sutured without special preparation, or the ends may previously be freshened, as seems to be expedient. Bevelling the ends by an oblique section will increase the area of the apposing surfaces. If the wound is to be closed, absorbable sutures should be used for approximation; moderately heavy catgut will often hold long enough to allow union, if the action of the tendon is prevented. If the wound is to be treated openly, silkworm-gut or silk may be used by preference. These sutures, usually two or three in number, are passed at a distance of about a fourth of an inch from the cut ends, and are to be left without tension. Great care must be used not to tear the stitches out by violence, or by using a needle large enough to split the tendon. The flat needle of Hagedorn is especially useful here. Sutures for relaxation should also be inserted at a greater distance, or the tendon may be temporarily held by a hare-lip pin, or by a suture of silver wire passed through the skin at the upper border of the wound. The relaxed position must be carefully maintained after the operation.

In the case of old injuries in which tendons have been divided, much improvement can often be effected by careful suture of the tendon. The cut ends of the tendon should be carefully dissected from the sheath to which they have formed adhesions, and should then be freshened before approximation by stitches. It is sometimes impossible to find the retracted tendon, and under these circumstances it has been found admissible to insert the distal end of the tendon into the body of one having a similar function. For example, the common flexor tendon supplying one finger may be spliced to that controlling another. This splicing is done by making a partial oblique division of the tendon and inserting the freshened end of the cut tendon in the space thus made. It has occasionally been found expedient to divide a less useful tendon and divert its muscle to a new function by uniting it to the stump of another severed tendon having a more important function. *F. A. Manning.*

TENESMUS. Syn.: Fr., Tenesme; Ger., Stuhlzwang; Gr., τεινεσμός, from τείνω, to stretch. By this term is understood a painful straining at stool, accompanied by spasmodic contractions of the sphincter ani muscle. It occurs when the rectum contains little or no fæces, but when the mucous lining of the bowel is in an irritable condition, arousing a sensation as of a large amount of material in the rectum, and causing an urgent desire to defecate; at the same time the irritable state of the mucous membrane covering the sphincter causes that muscle to contract violently. Usually a little mucus, often streaked with blood, with occasionally some fluid fæcal matter, is extruded in the intervals of the spasmodic closure of the sphincter. The straining is wholly involuntary, and is sometimes so severe as to cause prolapse of the bowel. Tenesmus is a symptom of any inflammatory condition of the mucous coat of the rectum or sphincter. It is commonly met with in dysentery, hæmorrhoids, and cancerous disease of the rectum; in intussusception involving the large intestine; in the rare instances of gouty inflammation of the lower bowel; in prolapse of the rectum, and occasionally in fistula or fissure of the anus.

As tenesmus is merely a symptom, the treatment should, of course, be directed to the cure of the causal disease. But the symptom is at times so distressing, that it demands treatment for itself, apart from that of the primary affection. A considerable measure of relief may often be afforded by small starch enemata to which a little laudanum has been added. Suppositories of opium and belladonna are also useful. Trousseau speaks highly of injections of a decoction of rhatany, of the strength of ʒ j. to the pint, after each stool. Very minute doses of gamboge have been recommended. Occasionally, ice suppositories or small enemata of cold water will serve a useful purpose, and at other times more relief may be afforded by warm injections or by hot applications to the anus. *T. L. S.*

TENESMUS, VESICAL. Syn.: Strangury; Lat., Urinæ stillicidium; Fr., Strangurie; Ger., Harnstrenge; Gr., στραγγουρία. This is a condition in which there is an almost constant, urgent desire to urinate, the act itself being accompanied by more or less pain. The urine, which sometimes contains more or less blood, is voided in very small quantities, sometimes drop by drop, and its passage is attended with severe pain in the perineum,

groins, hypogastrium, and often, in men, in the glans penis. The pain is lancinating in character, occurring in paroxysms, and is caused by the forcible spasmodic closure of the sphincter vesicæ; it may vary from a slight uneasiness to most excruciating torture. The desire to pass water is constant and imperative, yet the patient fears to yield to it, dreading the agony which the act causes.

Strangury is a symptom of irritability of the neck of the bladder, from whatever cause, and is pathognomonic of no special disease. It is often the most prominent symptom in various bladder troubles, and is usually the one for the relief of which the patient seeks advice. It is commonly present in cystitis, tumors of the bladder, vesical calculus or gravel, acute inflammation or congestion of the kidneys, hypertrophy and other diseases of the prostate, hyperacidity or alkalinity of the urine, etc. It sometimes occurs, with rectal tenesmus, in dysentery and other inflammatory diseases of the lower bowel. It is also caused by the ingestion or absorption of certain drugs, such as cantharides and turpentine, and it is a not uncommon experience to meet with more or less strangury after the application of a large fly-blister to any part of the integument.

When a patient presents himself, complaining of this symptom, it is necessary, of course, to search for the causal affection, and to institute the treatment proper for that condition. But it is often possible to greatly mitigate the severity of the vesical tenesmus, even before a cure of the affection, to which the irritability of the neck of the bladder is due, has been obtained. The urine should be rendered as bland as possible by means of demulcent drinks and by the ingestion of large quantities of water, so as to increase its dilution. If it is highly acid the citrate or acetate of potassium, in very dilute solution, may be given frequently; and if it is alkaline, benzoic acid will serve a useful purpose. The distress may likewise be moderated by opium and belladonna suppositories, by small enemata containing laudanum, or, better, by morphine hypodermatically administered. When practicable, the continuous hot sitz-bath will be found usually to give the greatest measure of relief, the patient being instructed to pass his water in the bath. Minute doses of cantharides or turpentine sometimes afford considerable relief, especially in the vesical tenesmus dependent upon enlarged prostate. Other drugs that have been recommended are gelsemium, bromide of potassium, aconite, veratrum viride, thymol, and various antiseptics and diuretics. *T. L. S.*

TENOTOMY. The first recorded instances of tenotomy were for the cure of muscular torticollis. The operation was performed by Roonhuysen in 1670, and again by Minnius, in 1685. Thilenius is said to have divided the tendo Achillis in 1684. In all these cases the division of the tendon was accomplished through an open wound. In 1816 Delpech made the first advance in the direction of a subcutaneous operation. He made a longitudinal incision in the skin, parallel with the course of the tendon, and at a little distance from it, and then effected the division of the tendon by means of a knife introduced through the wound so made. His operation was for the division of the tendo Achillis, and six years later, in 1822, Dupuytren performed tenotomy of the sterno-cleido-mastoid by the same method. Subcutaneous tenotomy, as it is now understood, was first performed by Stromeyer in February, 1831, and it is to him that we are indebted for the operation as it is practised at the present day. To Dieffenbach, also, is due much credit for his earnest advocacy of the procedure. Dr. Little, of London, who was himself a sufferer from talipes, and was successfully treated by Stromeyer, introduced the operation into England. In this country tenotomy was first performed by Dr. David L. Rogers, of New York City, in 1834. Dr. Detmold, of the same city, Dr. Mütter, of Philadelphia, and Dr. Richardson, of Kentucky, also contributed much to the general acceptance of tenotomy by the surgeons of this country.

The operation of tenotomy is indicated whenever contracture of a muscle exists as an impediment to the reduction of deformity. It is in the treatment of club-foot, however, that the operation finds its most frequent application. It is employed also in muscular torticollis, and in contractures of the muscles concerned in movements of the hip, knee, elbow, fingers, toes, etc.; in strabismus, in spasmodic stricture of the anus, and as a preliminary to the reduction of old dislocations. It should not, however, be employed indiscriminately, but only after a careful study of the indications in each individual case, and with a thorough appreciation of what it is desired to accomplish by means of it. In bony anchylosis, for example, it is evident that tenotomy alone will be useless, though it may sometimes be useful as a preliminary to osteotomy. In the malpositions occurring during the active stage of joint disease from reflex muscular action, tenotomy will be useless, and should not be attempted. In paralytic deformities, also, division of the tendon of a healthy muscle is productive of no permanent benefit.

The sins of commission are, however, less frequent as regards tenotomy than are those of omission, and it is, perhaps, of even greater importance to know when to perform the operation than when not to perform it. The rule laid down by Sayre, of "point-pressure," as an indication for the operation is a good one. It is not, however, infallible in every sense, for, while it will be perfectly safe and necessary to operate when reflex spasm is present, yet the writer has met with cases that were benefited by tenotomy, in which he was unable to elicit the spasmodic reflex. It is possible that in these cases the muscle might have been elongated by persevering manipulations, for stretching had been tried for a short time only; but the division of the tendon did no harm and certainly expedited matters. The following is the law referred to, as given by Sayre in his lectures on "Orthopedic Surgery, and Diseases of the Joints," p. 35.

Fig. 3820. — Tenotomes.

"Place the part contracted as nearly as possible in its normal position, by means of manual tension gradually applied, and then carefully retain it in that position; while the parts are thus placed upon the stretch, make additional point-pressure with the end of the finger or thumb upon the parts thus rendered tense, and, if such additional pressure produces *reflex contractions*, that tendon, fascia, or muscle must be divided, and the *point* at which the reflex spasm is excited is the point *where* the operation should be performed. If, on the contrary, while the parts are brought into their normal position by means of manual tension gradually applied, the additional point-pressure does *not* produce reflex contractions, the deformity can be permanently overcome by means of constant elastic tension, and the more you cut the greater will be the amount of damage done. This is an important law . . . for its application . . . is universal in deciding the question of cutting contracted tissues. Even when the parts can be completely restored to their normal position by means of manual force gradually applied, if this additional point-pressure produces pain or spasm, the contractured tissue must be cut before a complete cure can be effected."

Tenotomy may be performed either by cutting down directly upon the tendon through the skin and superficial tissues, or by what is known as the subcutaneous method. The latter is practically the only one employed at the present day, so that the word tenotomy, unless some qualifying term is added, is commonly understood to mean the subcutaneous division of a tendon.

The instruments employed are short, slender knives,

called tenotomes. They may be sharp-pointed or blunt, and may have a straight, convex, or concave cutting edge (Fig. 3820). The form of tenotome used is for the most part a matter of individual preference or custom. For most operations a straight, sharp-pointed instrument will be all that is necessary, though it is well to be provided with the curved and blunt-pointed instruments, which may be required in special cases. That part of the handle which corresponds to the cutting edge should always be marked in some way, in order to prevent confusion during the operation, when the blade is buried out of sight in the tissues. The strength of the tenotome is a matter of considerable importance, for, though of small size, it is often called upon to divide very dense tissues.

The other things necessary for the operation are two or three narrow strips of adhesive plaster, a couple of small sponges or a little absorbent cotton, thoroughly sterilized, and a compress made of sublimate or iodoform gauze.

The use of ether or chloroform is not advisable, except in the case of a very timid patient, for the operation is of very short duration, and it may be rendered entirely painless, if desired, by the previous injection of a few minims of a solution of cocaine. When, however, it is proposed to perform several subcutaneous sections in a young or nervous child, it may save some time and annoyance to have the patient under the influence of an anæsthetic. Chloroform is preferable to ether in the case of a young and healthy child. Nitrous oxide gas has been suggested as a specially appropriate anæsthetic in cases of tenotomy, as it is said to cause muscular contractions. Dr. W. A. Hunt has reported, in the *British Medical Journal*, an instance in which it was necessary to suspend the exhibition of the gas in a case of tooth extraction, because of the severe pain excited in a sprained ankle by the contraction of the muscles.

The operation of subcutaneous division of a tendon is a very simple one. The services of an assistant are often of great help, yet they are not usually absolutely necessary. The patient, anæsthetized or not, as the case may be, is placed in such a position that the tendon to be divided is readily accessible, and the limb is then manipulated so as to put the tendon on the stretch. A straight, sharp-pointed tenotome, previously sterilized, is now passed flatwise beneath the tendon and as close to it as possible, so as to avoid wounding any of the adjacent tissues. The knife is then turned with the cutting edge against the tendon and the latter is divided, with a rocking or sawing motion, in a direction toward the skin. It is necessary to use great care, when the tendon is nearly severed, in order to avoid cutting through the skin, and thus making an open wound. Some surgeons prefer to make the incision through the skin first, and then to introduce a blunt-pointed instrument and complete the operation with it. This is advisable in certain cases, when important vessels or nerves in the vicinity are exposed to injury from the point of the instrument. In some situations it will be found better to divide the tendon from without inward, in order to avoid the possibility of accidentally cutting through the skin. The operator must be sure that he has severed all the fibres of the tendon, otherwise the operation will fail in accomplishing the results desired. After the tendon has been cut through, the knife is withdrawn on the flat, in the same manner in which it was introduced, the finger being pressed upon the part so as to prevent the admission of air into the wound. A small pad of sublimate gauze is now placed over the point of incision, and retained by a couple of strips of adhesive plaster.

There are several accidents which may occur during or after the operation, and they should always be borne in mind as the best means of preventing them. These are, wounding an artery or vein, division of a nerve, or of the skin above the tendon, and inflammation and suppuration at the point of division of the tendon, resulting in non-union of the separated extremities. Non-union of the divided tendon may also occur from other causes, and sometimes has taken place most unexpectedly, when all the conditions seemed most favorable.

Much has been written about the repair of tendons after subcutaneous division, but the limits of this article forbid more than a very brief description of the process. Immediately after the operation there is a separation of greater or less extent between the divided ends of the tendon, the space between them being occupied by the sheath of the tendon, into which more or less blood has been effused. In the case of the tendo Achillis, which has no true sheath, the surrounding connective tissue fills the space. In a few days there is a pouring out of lymph and corpuscles, and a new formation of embryonic tissue takes place around the ends of the tendon and, to a less extent, between them. The extremities of the tendon become bulbous and are united by a cord of newly formed tissue, which is thinnest at its centre, growing thicker as it approaches the tendon at either end. This new material is gradually converted into fibrous tissue, which is barely distinguishable from true tendon tissue. The splice is thicker and more nearly resembles the tendon, if no motion of the parts has been permitted after the operation, and if no stretching of the new tissue has been done.

It was formerly taught that the divided ends of the tendon should never be allowed to separate, after tenotomy, any farther than could be helped, the fear being that union would be imperilled if such separation should take place. Even now it is, perhaps, the rule with most surgeons to approximate the ends of the tendon by retaining the parts in the position of the original deformity for some days, until it is supposed that union has taken place. Then, by means of gradual stretching, the newly formed tissue is elongated and the deformity is little by little overcome. That the deformity may be overcome by this method the general experience of surgeons has amply proved, but the plan of immediate restoration of the parts is much to be preferred.* In this method the deformity is at once overcome as far as it may be, and the parts are retained in their new position until firm union, by means of the new material between the separated ends of the tendon, has taken place. This method has several advantages in that it gives usually a better result, the newly formed tendon is larger and stronger, and the desired result is more quickly attained and at the expense of much less suffering to the patient. Care should, of course, be taken that the deformity be not over-corrected, so as to convert, for instance, a talipes equinus into a calcaneus, as has sometimes been done. This is, however, a rare accident, and usually, if not always, a preventable one. Non-union is no more liable to occur after immediate restoration than it is when the divided ends of the tendon are approximated. When tenotomy is performed as a preliminary to the operation of forcible breaking up of anchylosis, the external wound should be allowed to heal first, as otherwise the forcible stretching might readily tear the skin and convert the subcutaneous tenotomy into an open one. The reader will find a very clear statement of the arguments in favor of this method in a paper by Dr. Reginald H. Sayre, on "The Immediate Restoration of Parts to the Normal Position after Tenotomy," read before the Orthopedic Section of the New York Academy of Medicine, May 21, 1886, and published in the *Alabama Medical and Surgical Journal* of the same year.

The following are, in brief, the rules to be followed in making subcutaneous sections of individual tendons:

STERNO-CLEIDO-MASTOID.—In dividing either the sternal or the clavicular portion the tenotome is to be inserted beneath the tendon at a short distance above its insertion, and the section is to be made toward the skin. Care must be taken not to make the incision too high up, for fear of wounding the vessels in the neck.

TRAPEZIUS.—Division of this muscle, near its origin from the superior curved line of the occipital bone, is

* Scoutetten, as early as 1838, advised immediate restoration, though in a rather timid manner. He compared stretching of the newly formed tissue to the elongating of a bar of softened glass, and maintained that increased length in such a case was obtained at the expense of thickness. His example does not seem to have been followed by other surgeons of that day.

sometimes required. This is done by inserting the knife beneath the muscle, at a short distance from the bone, and dividing it toward the skin.

BICEPS.—This muscle may be divided just above the point where the bicipital fascia is given off. The tenotome should be introduced beneath the tendon, hugging it closely, in order to avoid the brachial artery, and the section is to be made toward the integument.

EXTENSOR MUSCLES OF THE THUMB.—These tendons may be severed where they form by their prominence the "tabatière." They are to be divided from within outward, care being taken to avoid the radial artery passing along the bottom of this triangle.

EXTENSOR COMMUNIS DIGITORUM. — These tendons may be divided on the dorsum of the wrist or of the hand, by introducing the knife above them and cutting down upon the bone. Of course, they should not be cut at the points where they pass over the joints.

FLEXORES CARPI.—Both the radial and the ulnar flexors have their corresponding arteries to the outer side, and the tenotome should be passed between the tendon and the artery, the edge turned away from the latter, and the tendon divided toward the integument.

FLEXORES DIGITORUM.—These tendons seldom require division, and as the operation is apt to be followed by severe inflammatory reaction it is better to avoid their section, if possible. They may be severed by introducing the knife between them and the integument and cutting down upon the bone beneath.

TENSOR VAGINÆ FEMORIS.—In the division of this muscle the knife may be introduced on either side of it, a short distance below its origin from the crest of the ilium, the section being made toward the integument.

SARTORIUS.—The knife is passed beneath the muscle, from its inner side, about two inches below the anterior superior spinous process of the ilium, and the division is made in an outward direction.

PECTINEUS.—Division is best made in a direction downward and inward, in order to avoid injury to the femoral vessels. The tenotome should be introduced at the outer edge of the muscle, about an inch from its origin.

ADDUCTOR LONGUS.—The knife is to be passed beneath the muscle, at its outer edge, a short distance below the pubes, and the division is to be made toward the integument.

QUADRICEPS EXTENSOR FEMORIS.—The tendon of this muscle can be divided a short distance above the patella, by an incision made from without inward. Some care is necessary to avoid opening the synovial sac of the knee-joint, which extends up under the tendon at this point.

HAMSTRING TENDONS.—The outer hamstring tendon is in close relation on its inner border with the external popliteal nerve. The knife should be passed between the tendon and the nerve, and the division made from within outward and toward the integument.

The inner hamstring tendons are, in their order from the inner side of the knee to the median line of the popliteal space, the sartorius, gracilis, semi-membranosus, and semi-tendinosus. The two latter are the ones that most frequently require division. Either or all of these tendons can be divided by the knife introduced at the inner side, and directed outward and toward the skin.

TENDO ACHILLIS.—The patient is placed in the prone position, an assistant flexing the foot strongly, so as to put the tendon on the stretch, and the tenotome is then introduced from the inner side, and close to the tendon, so as to avoid wounding the posterior tibial artery. The division is made toward the skin, care being taken that this is not wounded when the last fibres of the tendon are severed.

TIBIALIS ANTICUS.—The knife should be inserted on the outer side of the tendon, just in front of the internal malleolus, the division being made from without inward and toward the skin.

TIBIALIS POSTICUS.—The division of this tendon may be made in the leg or in the foot, the latter being more difficult, however, especially in young children. If the division is to be made in the leg, the child should be placed so that the foot rests on its external border. The tenotome is introduced a little less than an inch above the internal malleolus, and about midway between the malleolus and the border of the tendo Achillis, and the division is made from below upward toward the skin. If the incision is made too near the malleolus, there will be danger of wounding the internal saphenous nerve or vein, and if it is made too near the tendo Achillis, the flexor longus digitorum, the posterior tibial artery, or the posterior tibial nerve will be liable to be severed. In order to avoid these structures it has been proposed to divide the tendon in the foot. This may be done in a line drawn from the tip of the internal malleolus to the scaphoid bone, a short distance below and in front of the malleolus. There would seem, however, to be no special advantages in this procedure, and in children it is very difficult to make the section in the foot.

PERONEUS LONGUS.—The knife is to be introduced a short distance above the external malleolus, where the tendinous cord can usually be felt, and the section is made from behind forward and toward the skin.

PERONEUS BREVIS.—The tendon of this muscle lies just above and behind that of the long peroneal muscle. It may be divided at the same time that the section of the long peroneal is made. If, however, it is desired to sever it alone, the operation should be done in the foot. The tendon will be found in a line drawn from the posterior border of the external malleolus to the posterior extremity of the fifth metatarsal bone, from one-half to one inch in front of the malleolus. The peroneal tendons seldom require section, and it must be very rare indeed that one is to be divided without the other.

FLEXOR LONGUS POLLICIS.—This tendon may be divided at its most prominent part on the inner border of the foot. Care must be observed to avoid the internal plantar artery which runs along the inner border of the tendon.

FLEXOR LONGUS DIGITORUM.—The tendon of this muscle lies just behind that of the posterior tibial. The two tendons are usually divided simultaneously, but they may, with some care, be severed separately if it be desired. In division of this tendon great care will be required to avoid the posterior tibial vessels. These should, if possible, be pushed toward the tendo Achillis, and the knife may be introduced between the vessels (held out of the way by the finger) and the tendons of the posterior tibial and flexor longus digitorum muscles, a blunt-pointed instrument being used after the primary incision has been made through the skin; the flexor tendon is then carefully severed in a direction toward the integument. Parker advises the division of the tendon of this muscle, together with that of the posterior tibial, in the sole of the foot, just below the astragalo-scaphoid articulation, at a point where they cross each other.

These are the chief muscles that require tenotomy, excepting those of the eye; and for a description of the operations in this region the reader may consult the article on Strabismus in this volume of the HANDBOOK.

APONEUROTOMY, or fasciotomy, as it has been barbarously called, is the division, usually subcutaneous, of an aponeurosis, generally the palmar or plantar.

Palmar aponeurotomy, as proposed by Adams in the treatment of Dupuytren's contraction, consists of multiple subcutaneous sections of the fascia made at different points along the ridges caused by the contractured tissue. The knife, which should be small though strong, is to be introduced between the fascia and the skin, and the former divided from the surface downward. The sections are to be repeated at various points, until the bent finger can be straightened. As soon as the knife is withdrawn from the wound, the opening should be covered with a piece of plaster, a wad of antiseptic gauze, or something of the sort, before the next incision is made. Some care is necessary at times to avoid wounding the sheaths of the extensor tendons, an accident that is liable to be followed by considerable inflammation, in spite of the most thorough antiseptic precautions.

Plantar Fascia.—The division of this tissue is very frequently demanded in the treatment of club-foot. It

may be made at any point where the structure is most prominent, by introducing a tenotome beneath it, in the usual manner, flatwise, and cutting toward the skin.

MYOTOMY is the term employed to denote a subcutaneous section of the belly of a muscle instead of that of its tendon. It is very seldom performed, tenotomy being usually more convenient and much simpler. The same precautions against the admission of air and the wounding of neighboring structures are, of course, to be observed in myotomy as in tenotomy.

SYNDESMOTOMY, or the subcutaneous division of ligaments, is employed not uncommonly in the reduction of old dislocations in cases in which these structures offer very obstinate resistance to the replacement of the luxated bone. Syndesmotomy is advised and practised by Parker in the treatment of many cases of congenital talipes. He believes that the failures after tenotomy are often due to the fact that the ligaments are shortened, and do not yield sufficiently to allow of perfect reduction of the deformity. The subcutaneous division of ligaments is performed in the same manner and with the same precautions as that of tendons or muscles. It is necessary, however, to observe special care as regards antisepsis, since the joint is opened, and consequently very severe inflammation may follow the operation when carelessly performed.

The reader desiring more detailed accounts of the different subjects touched upon in this article may consult the following works, which are but a few among the more important of the many published:

Thomas L. Stedman.

TEPLITZ-SCHÖNAU is a well-known and popular health-resort, lying in a pleasant and well-protected valley, in Bohemia, at an elevation of about 700 feet above sea-level. The climate is rather mild, but there are apt to be sudden changes of temperature. There are eleven thermal springs at Teplitz, the waters of which contain a rather large proportion of mineral ingredients. The following is the analysis of the water. One litre contains:

	Gramme.
Potassium sulphate	0.017
Sodium sulphate	0.079
Sodium chloride	0.066
Sodium carbonate	0.403
Magnesium carbonate	0.013
Calcium carbonate	0.057
Silicic acid	0.046
Organic matters, etc	0.007
Total	0.688

The temperature of the different springs varies between 82° and 118° F.

The waters are employed externally only. Other therapeutic measures in use are mud-baths and the drinking of imported mineral waters.

The indications for the warm baths of Teplitz are gout and chronic articular and muscular rheumatism, neuralgia, various forms of skin disease, etc. The season extends from May to October, but many visit Teplitz even during the winter months. *T. L. S.*
